in the hope of discovering novel compounds serving as leads for the development of Western-style drugs. Moreover, recognition of each step of the ischemic cascade leads to the possibility of developing a new class of compounds that interferes with a specific mechanism or multiple mechanisms of ischemic injury. Based on the discussion of the sixteen compounds, there is the potential that stroke will become even more treatable, in particular these components have the potential to lead to a reduced permanent disability in patients with stroke.

Table 4.1. Compounds derived from natural medicines used in cerebral ischemia therapy

Source (Latin name)	Monomer Herbal component
Aloe	Aloe polysaccharide
Astragali Radix	Astragaloside IV and Calycosin
Chuanxiong Rhizoma	Tetramethylpyrazine
Crataegi Fructus	Maslinic Acid
Carthami Flos	Hydroxysafflor Yellow A
Chuanxiong Rhizoma	Ligustrazine
Curcumae Longae Rhizoma	Curcumin
Coptidis Rhizoma	Berberine
Erigerontis Herba	Breviscapine and Scutellarin
Ginkgo Folium	Ginkgolide B
Ginseng Radix et Rhizoma	Ginsenoside Rb1, Ginsenoside Rb3, Ginsenoside Rd and Ginsenoside Rg1
Leonuri Herba	Prehispnanolone
Magnoliae Officinalis Cortex	Magnolol
Notoginseng Radix	Maslinic Acid
Polygoni Cuspidati	Resveratrol
Puerariae Lobatae Radix	Puerarin
Picrorhizae Rhizoma	Picroside II
Rehmanniae Radix	Catalpol
Rhizoma et Radix	Resveratrol
Rhodiolae Crenulatae Radix et Rhizoma	Salidroside
Salviae Miltiorhizae	Tanshinone II A
Sinomenii Caulis	Sinomenine
Scutellariae Radix	Baicallin
Ziziphi Spinosae Semen	Jujuboside A

The results reflect significant progress and breakthroughs, which in future, through strong scientific research, have the ability to protect cerebral ischemia by compounds from natural medicines on the basis of the theory of Traditional Chinese Medicine and Western Medicine. Such efforts will also provide a direction for the further application and exploitation of new drug development in the treatment of cerebral ischemia.

Stroke Therapy in Traditional Medicine

Stroke is the first of the four major serious syndromes and the most acute disease in TEM. Stroke in TEM is called ‘wind stroke’ because it happens abruptly like the wind. The concept of stroke in TEM is quite different in many ways from that held by western medicine.

The syndrome is characterized by the sudden appearance of hemiplegia, deviated eyes and mouth, and impeded speech that may or may not start with sudden loss of consciousness. The theoretical systems of TEM are based on the doctrines of yin and yang, the five elements, viscera, and meridian systems. Gong and Sucher nicely reviewed the basic principles and classification of wind stroke in TEM [37].

Generally, the disease state is considered mainly as a destruction of the harmonious components of yin and yang. Wind stroke is considered to be caused either by weak internal strength (so-called ‘qi’) invaded by strong external ‘bad wind’ or by excessive internal ‘fire,’ such as anger, fatigue, heavy drinking, or dietary problems. Both can violate the harmonious negative-positive balance of the self, which eventually leads to stroke.

The treatment of wind stroke in TEM is aimed at creating equilibrium between the relative strength of the patient’s body resistance and the intensity of endogenous and exogenous pathogenic factors. Because wind stroke in TEM is caused by hyperactivity of liver yang, obstruction of the heart orifices by phlegm, excessive heat, or blood stasis.

The treatments in TEM include heat-clearing drugs, anti-rheumatics, drugs for dispersing exterior wind, drugs for promoting blood circulation, drugs for relieving phlegm, drugs for subduing interior wind, drugs for resuscitation, or tonics for deficiency syndromes, in accordance with the cause. Recently, these drugs have been demonstrated to have antioxidant, anti-inflammatory, and anti-glutamate effects. Usually, drugs for clearing away heat, inducing resuscitation, expelling wind, activating blood and removing stasis are used in the early acute stage, and drugs for invigorating and treating deficiencies are used in the later stage.

In the book *Tonggeuibokam*, one of the famous classics in TEM in Korea, 123 different prescriptions for stroke are recorded in the wind stroke section [38]. The herbs used in these prescriptions include, *Saposhnikovia Radix*, *Ligustichi Radix*, *Ginseng Radix*, *Angelicae Sinensis Radix*, *Paeoniae Radix*, *Arisaematis Rhizoma*, *Atylactylodis Rhizoma*, *Notopterygii Rhizoma seu Radix*, *Ephedrae Herba*, and *Scutellariae Radix*, in decreasing frequency. Herbs listed in Table 4.2 are used to treat neurological symptoms of strokes.

NEUROPROTECTION BY INDIVIDUAL HERBS AND THEIR COMPOUNDS

Cerebral ischemic injury is the result of an obstruction of blood flow in a major cerebral vessel, which will lead to a core of severely ischemic brain tissue that may not be salvaged.

However, the ultimate size of the brain infarct also depends on the penumbra, a zone of tissue around the core of the infarct where blood flow is maintained above a neuronal disabling level or the critical 20 to 25% of normal blood flow. Decreased blood flow leads to severe impairment of cellular function by disruption of ATP-dependent processes [39].

Ischemia and subsequent reperfusion provide circumstances that produce oxygen radical production. Several studies have suggested a relationship between cerebral ischemia and oxidative stress in humans [40, 41]. Therefore, antioxidants have been evaluated as neuroprotective agents in stroke [42]. Many herbs, especially those that contain flavonoids, are suggested to have antioxidant effects and possibly might be protective against brain injury caused by ischemia and reperfusion.

Many herbs have also been shown to have anti-inflammatory properties, and thus there is potential for novel anti-inflammatory agents to be identified from plant sources. For example, numerous flavonoid compounds have been associated with anti-inflammatory activity and may have the potential for use in the management of inflammatory disorders [43]. Glutamate toxicity and glucose deprivation is one mechanism of neuronal injury following ischemia. For a thousand years in TEM, some herbs have been used as tranquilizers for their central nervous system (CNS) inhibitory effects. Some of these herbs are known to have neuroprotective effects by the antagonism of excitatory amino acids, particularly glutamate, which is increased in the early post cerebral ischemia period and activates NMDA receptors. Individual herbs are comprised of many compounds, and it is therefore difficult to investigate the exact neuroprotective mechanism of many herbs, even though some show high efficacy in *in vitro* and *in vivo* ischemia models. The effective mechanisms of herbs may include antioxidant, anti-inflammatory, and anti-glutamate actions.

Natural Herbs Extracts and Their Active Compounds

More than 100 herbs have been used for stroke prevention and therapy in TEM. Described below are single herbs and their individual active compounds that have been demonstrated to have neuroprotective effects *in vitro* and *in vivo*.

Ginkgo Biloba

The leaves of *Ginkgo biloba* L. (Ginkgoaceae) have been used in TEM for respiratory and circulatory disorders, and its extract has been therapeutically used for several decades to increase peripheral and cerebral blood flow as well as for the treatment of dementia. *G. biloba* extract EGb761, a standardized extract of *G. biloba* leaves, contains about 24% flavonoid glycosides, primarily quercetin, kaempferol, isorhamnetin, 6% terpene lactones, 2.8 to 3.4% ginkgolides A, B, and C, and 2.6 to 3.2% bilobalide. EGb761 has shown favorable effects on cerebral circulation and neuronal cell metabolism [44, 45] and also exhibited antioxidant activity [46, 47].

EGb761 is neuroprotective against amyloid- and NO-induced toxicity *in vitro*. *G. biloba* extracts attenuate scopolamine-induced amnesia in rats [48], enhance memory retention in young and old rats [49], and improve short-term memory in mice [50]. *G. biloba* attenuates delayed neuronal death in the CA1 of the hippocampus in Mongolian gerbils [51] and is also associated with reduced stroke infarct volume in mice subjected to 45 min of tMCAo [52].

Table 4.2. Showing the some Natural Herbs used in the prevention and treatment of Cerebral ischemia

Name of the Herb	Scientific Name	Alternative names	Family/Group	Type of Neuroprotective effect	Part of herb used	Main components
Ginseng	Pinax Notoginseng	Notoginseng, Sanchi, Three-seven root, Mountain paint	Araliaceae	Anti-inflammatory, antioxidant	Roots	Ginsenosides (Gensenoside Rb1, Gensenoside Rg1), Saponins
Gingko	Gingko Biloba	Maiden hair tree, eun haeng	Ginkgoaceae	Antioxidant	Leaves	EGb761, Bilobalide, Quercitin, Ginkgolides, Keamferol
Scutellaria	Scutellaria baicalensis	Baikal skullcap	Lamiaceae	Antioxidant, anti-inflammatory	Roots	wogonin, baicalin, and baicalein
Salvia	Salvia miltiorrhiza	Red sage, Pinyin	Labiatae	Anticoagulant, Vasodilatory, Anti-inflammatory, Free-radical scavenging, Mitochondrial protection	Roots	Tanshinones
Acanthopanax	Acanthopanax senticosus	Devil's Bush, Touch-me-not, Eleuthero, Siberian Ginseng	Araliaceae	sedative, antioxidant, antihistamine, hypolipidemic, antistress, and immunomodulatory effects	Rhizomes (underground stem) and Roots	eleutheroside, chiisanoside, senticoside, triterpenic saponin, syringin, and flavones
Pueraria	Pueraria lobata	Kudzu	Legumnosae	Free-radical scavenging, anti-lipid peroxidation, and enhancement of SOD activity	Flower and roots	isoflavonoids like Puerarin, daidzin, and daidzein
Ligusticum	Ligusticum chuanxiong	Szechuan lovage Chuang xiang	Apiaceae	antioxidant, antifibrosis, antinociception, anti-inflammatory, antineoplastic	Rhizomes (underground stem) and Roots	Tetramethyl-pyrazine drug
Camellia	Camellia sinensis	Green tea	Theaceae	anti-inflammatory, anti-oxidant	Leaf buds, twigs	Catechins (Epigallocatechin) and flavonols (Theanine).
Rhodiola	Rhodiola rosea	golden root, roseroot, Aaron's rod, arctic root, king's crown	Crassulaceae	Anti-oxidant, antifatigue, antianoxia, and memoryenhancing	Rhizomes (underground stem)	salidroside, rosavin, rosin, rosarin, organic acids, terpenoids
Magnolia	Magnolia officinalis	Houpu, magnolia or magnolia-bark	Magnoliaceae	antihemostatic, antithrombotic, anti-inflammatory, anti-platelet	Root bark, seed, flower	Honokiol and magnolol
Angelica	Angelica sinensis	dong quai, dang gui, tang-kuei	Apiaceae	scavenging effect on peroxide and hydroxyl radicals and inhibitor of lipid peroxidation, Laxative, Sedative	Whole Herb	ferulic acid, ligustilide, angelicide, brefeldin A, butyridenephthalide, butyphthalide
Acorus	Acorus gramineus	Solander	Araceae	induces sedation, potentiates sleeping time, and antagonizes convulsion	Rhizomes (underground stem)	asarone

Name of the Herb	Scientific Name	Alternative names	Family/Group	Type of Neuroprotective effect	Part of herb used	Main components
Paeonia	Paeonia suffruticosa	Mudan, moutan or tree peony	Paeoniaceae	anti-oxidant, analgesic and anti-inflammatory	Root bark	Paeonol, Paeoniflorin
Corydalis	Corydalis yanhusuo	Yan Hu, Cordalis	Papaveraceae	antithrombotic, antihypertensive and anti-inflammatory	Tubers	Protopine, dehydrocorybulbine (DHCB), Tetrahydropalmatine
Huperzia	Huperzia serrata	Firmosses, fir-clubmosses	Huperziaceae	inhibitor of acetylcholinesterase	whole prepared moss	huperzine A
Phellodendron	Phellodendron amurense	Amur cork tree, huáng bò	Rutaceae	anti-inflammatory	Bark	berberine and worenine, flavonoids (diosmin), alkaloids (berberine, yatroriccin, palmatine), saponins and coumarins
Coptis	Coptis japonica	Gold-Thread Mouth-root, Canker-root	Ranunculaceae	antiphlogistic, sedative, antidotal, hemostatic	Rhizome, leaf with stalk, and rootlet	Berberine, magnoflorine, sanguinarine
Uncaria	Uncaria rhynchophylla	Cat's claw, Gambier	Rubiaceae	Antihypertensive, Anti-inflammatory, anticonvulsive, Monoamine Oxigenase-B (MAO-B) inhibitor and anti-spasmodic	Inner bark of the vine or root	Rhynchophylline
Gardenia	Gardenia jasminoides	Jasmine, danh-danh, Gardenia fruit, Cape jasmine fruit	Rubiaceae	anti-oxidant and anti-inflammatory	Fruit	Crocin and Crocetin
Menispermum	Menispermum dauricum	koumori-kazura, bat wine	Menispermaceae	anti-pyretic, analgesic	Roots and Rhizome	Dauricine, Dauriporphine, bisbenzylisoquinoline, aporphine, proporphine, protoberberine, and oxoisoaporphine.
Carthamus	Carthamus tinctorius	safflower plant, Fake Saffron, Alazor, American Saffron	Asteraceae	antioxidant, analgesic, anti-inflammatory and antidiabetic activities	Flower and oil from seeds	carthamin, Carthamidin, isocarthamidin, hydroxysafflor yellow A, safflor yellow A, safflamin C and luteolin
Schisandra	Schisandra chinensis	five flavor berry, Pinyin wi wèi zi, schizandra, gomish	Schisandraceae	Antihypertensive	Fruit	schisandrin, schisandrin derivatives and lignans schisandrol A, B and schisandrin A, B, C,

Bilobalide (Figure 4.1), a sesquiterpene trilactone constituent of *G. biloba*, reduces cerebral edema produced by triethyltin through preventing the uncoupling of oxidative phosphorylation. Pretreatment with bilobalide reduced the cerebral infarct area in MCAo mice [53].

Bilobalide protected the slices against hypoxia-induced phospholipid breakdown [54]. Bilobalide inhibited NMDA-induced phospholipase A2 activation and phospholipid breakdown in rat hippocampal slices [55]. Ginkgolides also had protective effects on focal cerebral ischemia, and its mechanism may be relative to its inhibition of platelet-dependent thrombosis and amelioration of hemorheological apartments [56]. Cumulative evidence indicates that *G. biloba* may have neuroprotective effects in brain ischemia rodent models, and bilobalide may be one of the main compounds responsible for this effect.

There is no convincing evidence from trials of sufficient methodological quality to support the routine use of *G. biloba* extract to promote recovery after stroke [57]. High-quality and large-scale randomized controlled trials are needed to test its efficacy.

Figure 4.1. Chemical structures of active compounds of neuroprotective herbs.

Scutellaria Baicalensis

The roots of *Scutellaria baicalensis* Georgi (Labiatae) have been used in TEM to treat inflammatory and cardiovascular disease. *S. baicalensis* contains three major polyphenolic components, namely wogonin, baicalin, and baicalein (Figure 4.1). These three polyphenols are as free-radical scavengers of hydroxyl, DPPH, and alkyl radicals [58]. Baicalein is the most effective compound of the three polyphenols tested in preventing glutamate toxicity [59] and is also known as a selective inhibitor of 12-lipoxygenase [60]. Baicalin also acts as a neuroprotectant during cerebral ischemia [61]. *S. baicalensis* and baicalein reduce ischemia-reperfusion brain injury and neutrophil infiltration in MCAo rats [62, 63].

S. baicalensis also protects CA1 neurons against transient 4-VO in rats. It also inhibits microglial TNF- α and NO production *in vitro* [64].

Wogonin, 5,7-dihydroxy-8-methoxyflavone, inhibits ischemic brain injury and improves behavioral dysfunction caused by permanent MCAo [65]. Wogonin has anti-inflammatory activities in various cell types and inhibits NO production by suppressing iNOS induction and NF- κ B activation in microglia [66].

Pueraria Thunbergiana, P. Lobata

The roots of *Pueraria thunbergiana* Benth (Leguminosae) are widely used in TEM for moderating alcohol abuse, for hypotensive, antipyretic, and analgesic effects and for treatment of the common cold. Puerarin (Figure 4.1), daidzin, and daidzein are three of the major isoflavonoid compounds isolated from the extract of *P. lobata*. *P. lobata* flavonoids increase the cerebral blood flow of anesthetized mice [67] and reduce the infarct volume in MCAo by increasing the activities of SOD [68]. Their isoflavonoids have potent inhibitory effects on PGE₂ production [69], and the antioxidant effect, partly dependent on free-radical scavenging, anti-lipid peroxidation, and enhancement of SOD activity [70]. Isoflavones in plants are known to have an estrogenic action. Puerarin has protective effects on cultured mouse cerebral cortical neurons damaged by Glu, NMDA, or KA [71].

Puerarin also shows neuroprotective effects in MCAo rats [72]. Puerarin clearance in normal rats was much faster than that in cerebral ischemia-reperfusion rats induced by MCAo and BCAo [73]. Genistein, a PTK inhibitor, prevented the increase of p-STAT3 and DNA binding activity in ischemic reperfusion injury at 4-VO [74]. It also prevented gerbil transient ischemia via a decrease in tyrosine phosphorylation of NR2B [75].

Magnolia Officinalis

The cortex of *Magnolia officinalis* (Magnoliaceae) has been used for the treatment of acute pain, diarrhea, coughs, and urinary problems in TEM. Honokiol and magnolol (Figure 4.1) are the main constituents of the bark of this herb and have a variety of pharmacological activities. Honokiol has been demonstrated to be an effective antioxidant [76]. It can protect animal tissues against lipid peroxidation [77, 78] serve as an antiplatelet drug [79], and it displays an anti-inflammatory effect in activated macrophages [80, 81]. Honokiol is a potent neuroprotective agent against focal cerebral ischemic injury by its antioxidant and antiplatelet aggregation effects [82, 83].

Magnolol (5,5'-diallyl-2,2'-dihydroxydiphenyl) inhibits intracellular calcium mobilization in platelets [84], relaxes vascular smooth muscle cells [85], and has antihemostatic, antithrombotic [86], anti-inflammatory, and analgesic effects [87].

A number of other effects of magnolol have also been found, including inhibition of prostaglandin D2 formation [87], suppression of nonselective vascular hypo reactivity to mediators [88], reduction of the formation of eicosanoid mediators [89], inhibition of neutrophil adherence [90], prevention of ischemic-reperfusion injury [91], and, most importantly, strong antioxidant activity [92]. Magnolol treatment appears to have a marked effect against heatstroke-induced cerebral ischemic insults [93].

Angelica Gigas, A. Sinensis

Angelicae Radix has been used as a sedative or a tonic and to treat disorders of menstruation in women, anemia, and menopause syndrome. *Angelica gigas* Nakai (Umbellaceae) is used in Korea, and *A. sinensis* (Oliv.) Diels is used in China.

A. gigas includes decursin, decursinol angelate, angelan, and decursinol. *A. gigas* protects mice against β -induced memory impairment [94]. *A. gigas* has antinociceptive effects on pain responses induced by TNF- α , IFN- γ , IL-1 β , glutamate, NMDA, or kainic acid [95]. Decursin ameliorates scopolamine-induced memory impairment in mice [96]. Decursinol and decursin protect primary cultured rat cortical cells against glutamate-induced oxidative stress by both reducing calcium influx and acting on the cellular antioxidative defense system [97]. *A. sinensis* contains ferulic acid, ligustilide, angelicide, brefeldin A, butyridenephthalide, butyphthalide, succinic acid, nicotinic acid, uracil, and adenine.

Extracts of *A. sinensis* showed a scavenging effect on peroxide and hydroxyl radicals and inhibited lipid peroxidation of the liver [98]. *A. sinensis* protects the brain from damage induced by transient forebrain ischemia in mice [99]. *A. sinensis* extract also has attenuating effects on amnesia induced by various drugs related to memory processes [100].

Salvia Miltiorrhiza

The root of *Salvia miltiorrhiza* Bunge (Labiatae) is red in color and was therefore used in TEM to treat related disorders of blood stasis with an action of quickening the blood and dispelling stasis. *S. miltiorrhiza* and its active ingredients, tanshinones and salvianolic acids, have anticoagulant, vasodilatory, anti-inflammatory, free-radical scavenging, mitochondrial protective, and other activities. Experimental studies have shown that *S. miltiorrhiza* dilated coronary arteries and scavenged free radicals in ischemic diseases.

Clinical trials also indicated that *S. miltiorrhiza* was an effective medicine for angina pectoris, myocardial infarction, and stroke [101]. Several studies have investigated possible mechanisms for the protective effect of *S. miltiorrhiza* against cerebral ischemia. *S. miltiorrhiza* attenuated dysfunction of VIP [102] and modified ischemic cell changes by modulating somatostatin [103] in cerebral ischemia. *S. miltiorrhiza* also decreased the size of the infarcted area after CCA ligation in gerbils by inhibiting presynaptic glutamate release and stimulating GABA release [104]. Inhibition of nitric oxide (NO) formation could explain the CNS protective effects observed with *S. miltiorrhiza* [105].

S. miltiorrhiza may offer an additional therapeutic approach to the management of stroke and ischemia. *S. miltiorrhiza* has been shown to offer protection against brain ischemia by reducing lipid peroxidation [106]. Pretreatment with *S. miltiorrhiza* reduced the infarct size in tMCAo-injured SD rats [107]. Tanshinones (Figure 4.1) are the major lipid-soluble pharmacological constituents of *S. miltiorrhiza*.

Brain infarct volume was reduced following treatment with tanshinone IIA and tanshinone IIB in MCAo mice [108, 109]. The therapeutic effect of *S. miltiorrhiza* may be partly due to its free-radical scavenging activities, Tanshinones or other structurally related compounds may have potential for further development as neuroprotective drugs. However, systematic review on randomized control trials comparing *S. miltiorrhiza* with other medicines does not support the notion that *S. miltiorrhiza* may be beneficial to disability improvement after acute ischemic stroke [110].

Acanthopanax Senticosus

The root and stem bark of *Acanthopanax senticosus* Harms (Araliaceae), also called Siberian ginseng, have been used as a tonic and adaptogen to strengthen *qi* in TEM and to treat rheumatic arthritis and stress-induced disease [111]. *A. senticosus* includes eleutheroside, chiisanoside, senticoside, triterpenic saponin, syringin, and flavones in its compounds [112], and it has sedative, antioxidant, antihistamine, hypolipidemic, antistress, and immunomodulatory effects. *A. senticosus* has a protective effect on CCl₄-induced liver toxicity via its antioxidative effect [113, 114]. The saponin isolated from the leaves of *A. senticosus* reduced myocardial infarct size in acutely ischemic dogs [115]. The liriodendrin, syringaresinol, the hydrolysate of liriodendrin, inhibited the LPS-induced production of NO, PGE₂, and TNF- α production by macrophages and decreased expression levels of iNOS and COX-2 enzymes [116]. It has been investigated whether water extracts of *A. senticosus* (100 mg/kg, i.p.) reduced infarct volume in tMCAo of SD rats. In this model, *A. senticosus* inhibited both COX-2 and OX-42 expression in the penumbral region at 24 h after MCAo [117]. These results suggest that *A. senticosus* has a neuroprotective effect via inhibition of inflammation, microglial activation, and antioxidative stress in brain ischemia.

Panax Ginseng

The root of *Panax ginseng* C. A. Meyer (Araliaceae), usually 4 to 6 years after cultivation, has been used as a general tonic or adaptogen and is frequently featured in TEM prescriptions.

Many studies have validated the empirical usage of ginseng over thousands of years for *qi*-invigorating and cardiovascular effects in TEM. The main active components of *P. ginseng* are ginsenosides, which have been shown to have a variety of beneficial effects, including anti-inflammatory, antioxidant, and anticancer effects [118]. *P. notoginseng*, from the same genus as *P. ginseng*, and its saponins exert a protective effect on ischemic brain damage *in vivo* [119, 120] and focal cerebral ischemia [121, 122]. Ginseng has neuroprotective effects in transient focal or global cerebral ischemia [123-125]. Red ginseng powder, which is steamed ginseng under pressure, also prevents delayed neuronal death in gerbils. Ginsenoside Rb1 (Figure 4.1) protects the brain from reversible focal brain ischemia in rats [126] and protects hippocampal CA1 neurons by scavenging free radicals [127]. Ginsenoside Rb1 stimulates the expression of the mitochondrion-associated antiapoptotic factor Bcl-x(L) *in vitro* and *in vivo* [128]. Ginsenoside Rg1 increases ischemia-induced cell proliferation and survival in the dentate gyrus of adult gerbils [129]. With reference to the studies conducted, the neuroprotective effects of ginseng on brain ischemia can be explained by multiple mechanisms, including scavenging free radicals and inhibiting the CNS. The compounds responsible for these neuroprotective effects require further investigation, but ginsenoside Rb1 could be one of the main neuroprotective compounds within the ginseng root.

Gardenia Jasminoides

The fruit of *Gardenia jasminoides* Ellis (Rubiaceae) has been used in TEM for the treatment of inflammation, jaundice, headache, edema, fever, hepatic disorders, and hypertension. Its pharmacological actions, such as protective activity against oxidative damage, cytotoxic effects, anti-inflammatory effect and fibrolytic activities, have already been demonstrated [130, 131].

Crocetin, a major component of gardenia fruits, was found to be a potent inhibitor of tumor promotion via antioxidant activity [132]. Another active component, crocin, exhibited a variety of pharmacological effects in mice, including inhibition of skin tumor growth, improvement of learning behavior previously impaired by ethanol [133], and prevention of long term potentiation caused by ethanol in rats [134]. It could be useful as a treatment for neurodegenerative disorders accompanied by memory impairment. Crocin also combats the serum/glucose deprivation-induced ceramide formation in PC12 cells caused by increasing GSH levels and prevents the activation of the JNK pathway, which is reported to have a role in the signaling cascade downstream of ceramide for neuronal cell death [135].

Paeonia Suffruticosa, P. Lactiflora

The root bark of *Paeonia suffruticosa* Andrews (Ranunculaceae) is a drug used in TEM as both an analgesic and an anti-inflammatory agent [136], and it is prescribed in various TEM preparations for the treatment of blood stagnation.

It has been reported to have strong superoxide and hydroxyl radical scavenging activity [137]. Its antioxidative effects are due to enhancing activities of SOD, CAT, and GPX [138].

Paeonol (Figure 4.1) inhibits cerebral ischemic injury by blocking increases in Ca^{2+} , decreases in SOD activity and the content of MDA, and improved Ca^{2+} -ATPase activity in ischemic brain tissue [139, 140]. A-benzoyloxy-paeoniflorin, an antioxidant monoterpene glycoside, from *P. suffruticosa* has potent radical-scavenging activity on the DPPH radical [141]. The root of *P. lactiflora* Palla has long been used to treat abdominal pain and blood deficiencies in TEM. The oral administration of *P. lactiflora* extract and paeoniflorin, a major constituent of peony root, attenuated spatial cognitive deficits caused by scopolamine in rats [142]. Paeoniflorin reduces the infarct volume as well as ameliorates the deficits in neurological symptoms caused by tMCAo in rats [143]. Paeoniflorin ameliorates memory disruption mediated by adenosine A1 receptor in rodents [144].

Coptis Japonica

The rhizomes of *Coptis japonica* Makino (Ranunculaceae), or *C. chinensis* Franch, have long been prescribed in TEM for the treatment of inflammation-related diseases such as gastrointestinal disorders and infectious or inflammatory diseases. *C. japonica* contains mainly alkaloids, including berberine, magnoflorine, sanguinarine, and phenolic compounds [145]. It has been considered to have antiphlogistic, sedative, antidotal, hemostatic, and antitumor properties. Berberine has been reported to exhibit several types of biological activities, and interest has been focused on its antioxidative potential [146, 147]. *C. japonica* extract and its active alkaloids were effective in an *in vivo* LPS plus ischemia reperfusion model that generated ONOO⁻ [148]. *C. chinensis* administered orally for 1 week improved scopolamine-induced learning and memory deficit in rats [149]. Although the active components of *C. japonica* that exert these bioactivities have not been fully elucidated, it has

generally been considered that its alkaloids, such as berberine, palmatine, and coptisine, contribute to these activities.

Camellia Sinensis (Green Tea)

Green tea contains antioxidant polyphenols such as catechins and flavonols. Most of the experimental and epidemiological studies concerning green tea effects have been targeted at its possible cardiovascular, anti-inflammatory, and anti-carcinogenic effects, which have been linked to the antioxidant/pro-oxidant properties of its polyphenol constituents [150, 151].

Daily ingestion of tea as an antioxidant has also been reported to prevent stroke. Green tea extract orally administered to Wistar rats for 3 weeks before induction of ischemia by occlusion of middle cerebral arteries and reperfusion minimized the eicosanoid accumulation and oxidative damage in addition to the reduction of neuronal cell death [152]. Green tea extract prevented cerebral ischemia damage caused by global ischemia-reperfusion in Mongolian gerbils [153]. (-)-EGCG has potent antioxidant properties in a green tea polyphenol and had a neuroprotective effect against neuronal damage following global ischemia in Mongolian gerbils [154]. Theanine (Figure 4.1), a flavors component of green tea, has a neuroprotective effect against neuronal death in transient brain ischemia. The mechanism of the neuroprotective effect of theanine is related not only to the glutamate receptor but also to other mechanisms such as the glutamate transporter [155].

Huperzia Serrata

Huperzia serrata, a source of huperzine A (Figure 4.1), has been used for centuries in TEM to treat fever, inflammation, blood disorders, and schizophrenia. Huperzine A acts as a potent, highly specific and reversible inhibitor of acetylcholinesterase that crosses the blood–brain barrier. Its potency of acetylcholinesterase inhibition is similar or superior to that of physostigmine, galanthamine, donepezil, and tacrine [156, 157]. Huperzine A protected PC12 cells against OGD-induced toxicity, most likely by alleviating disturbances of oxidative and energy metabolism [158]. Huperzine A treatment is protective against both brain injury and spatial memory impairment in a hypoxic ischemic brain injury of a neonatal rat model [159, 160]. Huperzine A protects against diverse neurodegenerative states observed during ischemia or Alzheimer’s disease by blocking NMDA ion channels [161]. Subchronic oral administration of huperzine A after global ischemia in gerbils significantly reduced memory impairment, reduced neuronal degeneration in the CA1 region, and partially restored hippocampal choline acetyltransferase activity [162].

Acorus Gramineus

The rhizomes of *Acorus gramineus* Solander (Araceae) have been used for the improvement of learning and memory and are often included in the TEM prescriptions for stroke [163, 164]. Water extract or volatile oil from *A. gramineus* induced sedation, decreased spontaneous activity, potentiated pentobarbital-induced sleeping time, and antagonized pentylenetetrazole-induced convulsion in mice [165, 166]. The interactions of *A. gramineus* with the central dopamine (D1 and D2) receptors and the GABA binding site of GABAA receptors were thought to mediate these central inhibitory actions. The methanol extract and the essential oil from *A. gramineus* inhibited excitotoxic neuronal cell death in primary

cultured rat cortical cells [167, 168]. One active principle was identified as asarone (Figure 4.1), a major essential-oil component in the rhizomes of *A. gramineus* [169].

Carthamus Tinctorius

Carthamus tinctorius, the flower of the safflower plant, has been used extensively in TEM for its purported ability to improve cerebral blood flow. *C. tinctorius* protected against excitotoxicity of glutamate, NMDA, kainate, quisqualate and against neuronal degeneration caused by simulated ischemia [170]. *C. tinctorius* exerted significant neuroprotective effects on rats with focal cerebral ischemic injury [171]. *C. tinctorius* reduced cell damage and the formation of peroxidation products after bilateral ligation of the common carotid arteries in rats [172].

Bombycis Corpus

Bombycis Corpus (BC) is a *Bombyx mori* larva (silk moth larva, Bombycidae) killed by infecting with the fungus *B. bassiana*. It has been used in TEM to treat palsy, headache, convulsion, and speech problems induced by stroke and tremor. Several sterols have been isolated from BC. BC has a protective effect against A α -induced cytotoxicity in cultured astrocyte cells through the inhibition of lipid peroxidation and protection of antioxidative enzymes such as catalase, SOD, GSH-Px, and glutathione-S transferase [173].

Sphingolipids from BC also have neurotrophic effects as shown by examining PC12 cell neurite outgrowth [174]. Pretreatment with BC protected primary hippocampal cultures from embryonic day 18 embryos against NMDA-induced toxicity [175]. BC contributes to protect human brain by inhibiting the release of glutamate.

Menispermum Dauricum

Menispermum dauricum DC. (Menispermaceae) roots are used for treating sore throats, colitis, dysentery, and rheumatic arthralgia in TEM. This herb contains some alkaloids belonging to various classes such as bisbenzylisoquinoline, aporphine, proporphine, protoberberine, and oxoisoaporphine. Phenolic alkaloids from *M. dauricum* could attenuate injury caused by left anterior descending coronary artery and BCAo in rabbit by lipid peroxidation and enhance the activity of SOD [176].

Daurisoline, which has been isolated from *M. dauricum*, crosses the blood–brain barrier and will, therefore, facilitate the functional characterization of brain calcium channels in granule cells freshly isolated from rat cerebellum as well as the exploration of P-type calcium channels as possible drug targets [177].

Cnidium Officinale*, *Ligusticum Chuanxiong

The rhizome of *Cnidium officinale* Makino (umbelliferae) is one of the important traditional medicines used for the treatment of female genital inflammatory diseases. *C. officinale* contains a variety of volatile phthalide derivatives that have been shown to have pharmacological activities including sedative, antianemia, antifungal, smooth muscle relaxing, anti-inflammatory, analgesic, and anticomplement activities.

Falcarindiol (1,9-Heptadecadiene-4, 6-diyne-3, 8-diol), which was isolated from *C. officinale*, and the ethyl acetate-soluble fraction of *C. officinale* reduced NO production and suppressed iNOS expression in BV-2 cells and primary microglia cells. The inhibition of

excessive NO production played an important role in neuronal cell death in LPS-treated rat hippocampal slice cultures [178, 179].

The rhizome of *Ligusticum chuanxiong* Hort. has also been used in TCM for the same applications as *C. officinale*. *L. chuanxiong* inhibited platelet activation in bilateral common carotid artery occlusion (BCAo) in rabbits and corrected the TXA2- PGI2 imbalance in plasma after cerebral ischemia [180]. *L. chuanxiong* reduced cell damage-formation of peroxidation products after bilateral ligation of the common carotid arteries in rats [181]. Tetramethylpyrazine, a drug originally isolated from the rhizome of *L. chuanxiong*, has been used routinely in China for the treatment of stroke and angina pectoris. Tetramethylpyrazine has therapeutic potential for the treatment of dementia caused by cholinergic dysfunction and/or decrease of cerebral blood flow. Tetramethylpyrazine pretreatment showed a neuroprotective effect on cerebral ischemia in gerbils [182].

Rhodiola Rosea

The root of *Rhodiola rosea* L. (Crassulaceae) is used as a hemostatic and tonic and for contusions. *Rhodiola* plants demonstrated antifatigue, antianoxia, and memoryenhancing effects. The major compositions of rhizomes of *R. rosea* are phenols such as salidroside and its glycan tyrosol, and cinnamic glycosides such as rosin, rosavin, and rosarin.

Other important constituents are flavonoids, tannins, gallic acid and its esters and essential oils. Administration of *R. rosea* extract for 10 d yielded protection against impairment in memory, as assessed by step-down passive avoidance, induced by electroshock in rats [183]. Several constituents of *R. sacra* and *R. sachalinensis* showed protective effects against beta-amyloid toxicity, oxidative stress, and apoptosis [184]. Phenolic compounds exhibited significant scavenging effects against DPPH free radicals [185]. *R. sachalinensis* treatment reduced infarct volume and attenuated COX-2 induction and microglial activation after tMCAo in rats [186].

Schisandra Chinensis

The fruit of *Schisandra chinensis* Baillon (Schisandraceae) is used in TEM to improve liver and kidney function as an antitussive, tonic, and sedative agent. *S. chinensis* inhibited TBARS formation *in vivo* [187]. The active components of *S. chinensis* are schisandrin derivatives and lignans schisandrol A, B and schisandrin A, B, C, protect primary cultures of rat cortical cells from glutamate-induced toxicity [188]. Pretreatment with schisandrin B also protected against cerebral toxicity induced by tetrabutylhydroperoxide [189].

Corydalis Yanhusuo

The tubers of *Corydalis yanhusuo* W. T. Wang (Papaveraceae) are used in TEM mainly as an analgesic in the treatment of gastric and duodenal ulcer, rheumatism, and dysmenorrhea. *C. yanhusuo* is one of the medicinally important species of *Corydalis*. The tubers are a source of pharmacologically important alkaloids having analgesic [190], antithrombotic [191], antihypertensive [192], and anti-inflammatory effects [193]. Protopine, a component of *C. yanhusuo*, has an inhibitory activity on platelet aggregation [194], and DL-tetrahydropalmatine has a neuroprotective effect in heatstroke-affected rats [195]. It also inhibits calcium anion entry into cells to prevent neuronal death in ischemia-reperfusion rats [196]. It reduced cerebral infarct lesion in focal ischemia-reperfusion injured rats [197].

Phellodendri Cortex

The stem bark of *Phellodendron amurense* Ruprecht (Rutaceae) has long been used in TEM for the treatment of inflammation and fever as a traditional herb medicine having anti-inflammatory, immunostimulatory, and antitumor activities.

It contains some alkaloid components such as berberine and worenine. The antioxidant, anti-inflammatory, and antityrosinase activities of *P. amurense* have been studied [198].

Phellodendri can scavenge superoxide radical (O_2^-) generated through the hypoxanthine-oxidase system and hydroxyl radical OH generated through the Fenton reaction and can inhibit lipid peroxidation induced by the hydroxyl radical generation system [199].

Uncaria Rhynchophylla

The branch of *Uncaria rhynchophylla* (Miq.) Jacks. (Rubiaceae) has been used in TEM for relief of dizziness and treatment of tremors and convulsions [200]. It has antispasmodic effects on smooth muscle and lowers blood pressure [201, 202]. The anticonvulsive effects of this herb have been experimentally demonstrated in KA-treated rats [203].

It inhibited an increase of lipid peroxide levels evoked by ferric-chloride-induced epileptic seizures in rats [204]. Recent studies demonstrated that the extract of *U. rhynchophylla* has a neuroprotective effect on global cerebral ischemia-induced neuronal damage in rats by reduction of COX-2 mRNA and protein level *in vivo* [205].

Rhynchophylline, a major tetraacyclic oxyindole alkaloid isolated from *Uncaria* species, is known to have a protective effect against glutamate-induced neuronal cell death [206]. Both the extract of *U. rhynchophylla* and rhynchophylline ameliorated transient cerebral ischemia-induced spatial memory deficit in mice [207].

Gynostemma Pentaphyllum

Gypenosides, saponins isolated from *Gynostemma pentaphyllum*, are widely used as they are thought to have a wide range of health benefits, including inhibition of inflammation and prevention of cardiovascular disease, due to antioxidant and lipid-lowering properties [208, 209]. Gypenosides decreased injury of DNA and RNA in rat neurons in the 4-VO cerebral ischemia-reperfusion model [210].

Gypenosides suppressed NO synthesis in murine macrophages by inhibiting iNOS enzymatic activity and attenuating NF- κ B-mediated iNOS protein expression, thereby invoking a mechanism by which gypenosides may exert their therapeutic effects [211].

Spiraea Japonica

Spiramine T is an atisine-type diterpene alkaloid isolated from the *Spiraea japonica* var. *acuta* (Rosaceae). It was shown to have neuroprotective effects on cerebral ischemia-reperfusion injury produced by bilateral occlusion of the common carotid arteries in gerbils, and its mechanism might be related to reducing calcium accumulation and lipid peroxidation [212]. Spiramine T reduced the content of lipid peroxide, increased glutathione peroxidase activity, and inhibited the increase of nitric oxidase activity and NO production in the cortex during global forebrain ischemia reperfusion in gerbils [213].

Dioscoreae Rhizoma

The root of *Dioscorea batatas* Decne or *D. japonica* Thunb, called Yam, has been used in TEM for the treatment of diarrhea, cough, dyspnea, leucorrhagia, frequent urination, and diabetes. It is composed mainly of starch with small amounts of mucilage, dioscin, and dopamine.

Dioscoreae Rhizoma was reported to have antisenility [214] and antioxidant activities [215]. My group found that water extracts of *D. japonica* protected against hippocampal cell death in 4-VO of Wistar rats.

Withania Somnifera

Withania somnifera, referred to as *Aswagandha* in the Indian system of medicine, is a central nervous system active herb that has been used for various neurological disorders. Studies with *W. somnifera* have indicated that it exerts an antiaging effect anxiolytic and antidepressant activity [216]. The other pharmacological actions exerted by *W. somnifera* include anti-inflammatory, antistress, hemopoietic immunomodulatory, and antioxidant effects [217, 219]. *W. somnifera* decreased MDA levels and hemispheric lesion area in focal cerebral ischemia induced by MCAo [220].

Curcumin

Curcumin, an active constituent of the rhizome *Curcuma longa*, was demonstrated to have antioxidant potential in many *in vitro* and *in vivo* studies. Curcumin has a neuroprotective effect in tMCAo [221] and bilateral common carotid artery occlusion [222] that is mediated through its antioxidant activity. So a variety of herbs and prescriptions have been demonstrated to have neuroprotective effects *in vivo* and *in vitro* that may be relevant to the treatment of stroke. The majority of *in vivo* studies have been performed in rodent ischemia models, MCAo as focal ischemia, and 4-VO and 2-VO as global ischemia. The mechanisms of neuroprotective herbs in TEM are suggested to be antioxidant, anti-inflammatory, and anti-glutamate effects; however, it is difficult to be precise about mechanisms as the herbs have so many active compounds with disparate mechanisms.

In conclusion, the pharmacological activities of herbs often appear to reflect their traditional uses. The approach for screening herbs to investigate for treatment of stroke is a relatively successful method for the identification of herbs and single compounds.

Future Directions

The development of effective plant-based products for improving human brain function is constrained by a number of issues, including a need to definitively identify relevant active components and understand synergies within them and an inability to adequately standardize replicable extracts. It is evident that insects such as *Drosophila* and the honeybee are sensitive to modulation by a full range of pharmacological agents. However, insect behavioral studies have only involved secondary metabolites either as a consequence of using them as simple tools for the modulation of specific neurotransmitter targets or alternatively in insect models of drug abuse and addiction. It would seem appropriate that insect models could be utilized as simple, economical, time-efficient, and ethically acceptable tools for investigating the

neuronal and behavioral consequences of individual phytochemicals and complex mixtures. It is also evident that there are many viable terpene/phenolic extracts that may have beneficial effects on CNS function without the toxicity associated with psychoactive alkaloids. These may include complex chemical mixtures that attract symbiotic insects and potentially offer them cognitive benefits (106).

However, many phytochemicals simply do not function effectively as single molecules and there are many examples of synergies within and between the chemical groups. Insect models may provide ideal starting points for disentangling these synergies prior to animal and human studies.

Many secondary metabolites are also expressed as a consequence of environmental stressors, and an increased understanding of the many and varied ecological roles of secondary metabolites should, in the future, make it practical to upregulate and standardize the levels of desired active components by introducing a variety of stressors such as herbivore attack, salinity, UV light, bacteria, or fungi in carefully controlled environments.

Finally, the vast majority of the voluminous research relating to the topics briefly reviewed above is conducted in entirely discrete discipline “silos.” In terms of research relevant to brain function, the vast majority is basic laboratory research conducted in vitro/ vivo in an entirely atheoretical context, often with parent molecules or chemical concentrations that are highly unlikely to be seen in the human brain. Asking the simple question of why plant chemicals modulate brain function can only serve to focus some of this huge research effort, with the integration of thoughts and concepts from a diverse range of disciplines, including molecular biology/biochemistry, plant science, zoology, entomology, pharmacology, medicine, neuroscience and psychology potentially offering an intellectual synergy that might move this area a step forward.

Chapter 20

POLYPHENOLS FROM NATURAL HERBS IN NEUROPROTECTION

Manzoor A Mir^{1,*}

ABSTRACT

Plant polyphenols are dietary components that exert a variety of biochemical and pharmacological effects. Recently, considerable interest has been focused on polyphenols because of their antioxidant, anti-inflammatory, and anti-proliferative activities. Oxidative stress is thought to be a key event in the pathogenesis of cerebral ischemia. Overproduction of reactive oxygen species during ischemia/reperfusion could cause an imbalance between oxidative and anti-oxidative processes. Reactive oxygen species can damage lipids, proteins, and nucleic acids, thereby inducing apoptosis or necrosis. There is increasing evidence supporting the hypothesis that plant polyphenols can provide protection against cerebral ischemia and neurodegenerative diseases. These polyphenols exert their neuroprotective effects through different mechanisms and may function at several cellular levels, including direct interaction and modulation of enzymatic activities and the regulation of signaling pathways with implications for cell survival and death. The mechanisms include the reduction of neuroinflammation via attenuation of the release of cytokines, such as interleukin-1 β and tumor necrosis factor- α and downregulation of the pro-inflammatory transcription factors such as NF- κ B; antioxidant activity, mainly through the inhibition of the NADPH oxidase and subsequent reactive oxygen species generation; an activatory effect on endothelial and inhibitory action on both neuronal and inducible nitric oxide synthase activity and subsequent NO production; and the potential to modulate signaling pathways such as mitogen-activated protein kinase cascade and cAMP response element-binding protein leading to the improvement of memory and cognitive performance. The elucidation of polyphenol activities at the molecular level may lay the foundations for new pharmacological approaches in relation to neurodegeneration. Here in this chapter we will provide a detailed account of different

polyphenols, their components, molecular mechanisms underlying the potential health promoting effects in relation to cerebral ischemia and other neurodegenerative diseases.

ROLE OF POLYPHENOLS IN NEUROPROTECTION

Phenolics and Polyphenols

Phenolics are ubiquitously found across the plant kingdom, with ~10,000 structures identified to date. Phenolics range from simple low-molecular weight compounds, such as the simple phenylpropanoids, coumarins, and benzoic acid derivatives, to more complex structures such as flavanoids, stilbenes, and tannins. Of these, the flavonoids represent the largest, most diverse group, encompassing some 6000 compounds, all of which share a common underlying structure of two 6-carbon rings, with a 3-carbon bridge, which usually forms a 3rd ring. Flavanoids can then be subdivided according to modifications of this basic skeleton into chalcones, flavones, flavonols, flavanones, isoflavones, flavan-3-ols, and anthocyanins [1].

Research on polyphenolic compounds has started to accelerate with the discovery of the “French paradox” (i.e., the low incidence of coronary heart disease observed in France in association with red wine consumption and intake of a high-fat diet) [2]. This effect seems to be attributed to the polyphenols in red wine. Recently, important epidemiological studies have found that a high consumption of fruits and vegetables can also lower the risk of ischemic stroke [3-5]. The studies regarding health benefits of polyphenols have largely focused on heart disease and cancer. However in recent years polyphenols have got increased attention whether they can offer antioxidant and anti-inflammatory benefits to the brain and have possible preventive effects on stroke and neurodegenerative diseases. For example, initial studies have emerged to show the ability of polyphenolic compounds to improve neurological functions in aging [6-7] and to ameliorate oxidative and inflammatory damages owing to chronic alcohol abuse [8].

A wide range of phenolic compounds in the CNS function, directly interact with neurotransmitter systems. As an example, in animal models, a diverse range of individual and combined flavonoids that occur in traditional medicinal extracts exert sedative/ anxiolytic effects via direct binding to GABAA receptors [9-10], cognitive enhancement via antagonistic GABAA receptor binding and resultant cholinergic upregulation [11], and antidepressant effects via monoamine oxidase inhibition and resultant increases in levels of 5-HT, DA, and noradrenaline in select brain areas [12]. In mammals and other vertebrates, phytoestrogens modulate hormonal systems, and therefore brain function, via a variety of mechanisms [13].

Polyphenols are found in most plant-derived foods and beverages. There are over 8000 polyphenolic structures identified in plants. Polyphenols add to the sensory and nutritional qualities of plant foods. Polyphenols are often involved in the plant's defensive response against different types of stress such as ultraviolet radiation, pathogens, and physical damage. Because plants usually produce these polyphenols as a defensive mechanism, environmental conditions such as soil type, sun exposure, and rainfall along with other factors such as genetics factors, germination, degree of ripeness, processing and storage, and species variety can have effect on the polyphenol concentration. All polyphenols contain an aromatic ring

with one or more hydroxyl group. Most also have at least one sugar residues (glycosides) attached to the hydroxyl groups. They are classified into different groups depending on the number of phenol rings and chemical groups bound to the rings [14-16]. Polyphenols are a group of naturally occurring phytochemicals which are present in high amounts in fruits, vegetables, and natural products and are characterized by the presence of multiple hydroxyl groups on aromatic rings. These compounds are divided into two main categories: the flavonoids and nonflavonoids, based on the number of phenol rings and the way in which these rings interact (Figure 5.1).

Polyphenols contain a wide range of molecule sizes. Polyphenols, such as phenolic acids, are simple compounds, whereas the tannins are highly polymerized molecules. Flavonoids make up most of the polyphenols and they form the most important single group of polyphenols [14]. Table 5. 1 summarizes the main classes of polyphenols, some representative phenolics in the groups, and their dietary sources. Polyphenols are usually recognized for their antioxidant capabilities. Phenolic antioxidants have been shown to inhibit the oxidation of lipids and other molecules and protect against free radicals [14, 17]. Polyphenols can react with radicals to form polyphenol radicals. The polyphenol radical is more stable and less reactive because of the ability of the phenol group to absorb extra electrons. Most polyphenols are conjugated by methylation, sulfation, or glucuronidation during metabolism. The antioxidant capability could be determined by the type of conjugate and its location on the polyphenol structure. This might be why certain polyphenols are better at scavenging superoxides, whereas others can scavenge the highly reactive oxygen-derived radical peroxynitrite. Their antioxidant capacity may also correlate with their ability to chelate metals. Specific polyphenols can chelate iron and possibly prevent the formation of free radicals by iron [18-21].

Polyphenols have been shown to have several other actions in addition to their antioxidant ability. Evidence show that they can inhibit the activities of several enzymes, including lipoxygenase, cyclo-oxygenase, xanthine oxidase, phospholipase A2, ATPases, aldole reductase, phosphodiesterases, topoisomerase I and II, protein kinase C, phosphoinositide 3-kinase, Akt/PKB, (protein kinase B) and mitogen-activated protein (MAPKs) kinases (MAPs) [18, 22-23]. Some polyphenols have weak estrogenic properties and others can inhibit the enzymes involved in estrogen metabolism, aromatase, and 17-hydroxysteroid oxidoreductase [23]. The reduction of several diseases has been linked to polyphenols. Cardioprotection and a reduction in certain types of cancer have correlated with consumption of phenolic antioxidants [14, 23].

There is also evidence for polyphenols to be antiallergic, antiviral, antibiotic, antidiarrheal, antiulcer, and anti-inflammatory agents. Polyphenols have been used to treat hypertension, vascular fragility, allergies, and hypercholesterolemia [14, 16-17]. Polyphenols have also been implicated in the prevention of neurodegenerative diseases.

Polyphenols protect neurons against oxidative stress thought to one of the main causes of neurodegenerative diseases. Even a 10-fold higher concentration of ascorbate did not protect neurons similar to polyphenols [17]. Polyphenols attenuate ischemia-reperfusion injury by interfering with inducible nitric oxide synthase activity, inhibiting lipid peroxidation, decreasing the number of immobilized leukocytes during reperfusion, and reducing complement activation which results in a diminished inflammatory response [18]. Most importantly, in addition to their antioxidant actions, they also influence neuroprotective and neurorestorative signal transduction mechanisms [21]. Epidemiological studies show an

inverse relationship between stroke and polyphenol consumption [15]. The dietary intake of polyphenols varies greatly among different societies. Isoflavone intake as a result of soy consumption ranges from 20 to 240 mg for Asians and from 1 to 9 mg in the United States and Western populations [16, 23].

The evidence presented in this section suggests the potential of polyphenols in both preventive and therapeutic usages for cerebral ischemia/reperfusion injuries. Furthermore, no toxic or other adverse side effects were reported with the dietary use of high concentration of polyphenols, although regulated clinical trials have not been performed. In addition, their bioavailability, absorption, and metabolism also require more studies, especially in humans. It would be particularly important to compare individual polyphenols with extracts of fruits, beverages, and vegetables in preclinical and clinical projects and to further investigate possible mechanisms of their effects. Numerous studies have indicated that compounds in an extract can act synergistically so it would be advantageous to use multiple polyphenols in the treatment of stroke. In particular, when stroke symptoms appear, a substantial damage has already taken place in the brain. Therefore, treatments have to start as early as possible in order to reduce further neurodegeneration and promote regeneration. However, the preventive use of plant products will be likely the most effective strategy for the treatments of stroke and other age-related neurodegenerative disorders.

Figure 5.1. Structures of polyphenols. Polyphenols are a group of naturally occurring phytochemicals which are present in high amounts in fruits, vegetables, and natural products and are characterized by the presence of multiple hydroxyl groups on aromatic rings. These compounds are divided into two main categories, the flavonoids and non-flavonoids, based on the number of phenol rings and the way in which these rings interact. For the flavonoid group, the major differences between the individual groups arise from the hydroxylation pattern of the ring-structure, the degree of saturation of the C-ring, and the substitution of the 3-position. HBAs, hydroxybenzoic acids; HCAs, hydroxycinnamic acids.

Table 5.1. Major Subclasses of Polyphenols, Compounds, and Food Sources

Polyphenol Group	Name of Compound	Sources of the Polyphenol compounds
Flavonoids		
Flavonols	Quercetin, myricetin, kaempferol	Onions, apples, kale, red wine, green and black tea, broccoli, berries
Flavanones	Hesperetin, naringenin, eriodictyol	Citrus fruit, tomatoes, mint
Flavanols (Proanthocyanidins and catechins)	Epicatechin, epigallocatechin, epicatechin-3-gallate, epigallocatechin-3-gallate	Apricots, green and black tea, red wine, chocolate
Anthocyanins	Cyanidin, pelargonidin, malvidin	Strawberries, other berries, grapes, wine, tea, eggplant, cabbage,
Isoflavonoids (phytoestrogens)	Genistein, diadzein, glycitein	Lentils, chickpeas, alfalfa, clover, flaxseed, soybeans
Flavones	Apigenin, luteolin, diosmetin, tangeretin, nobiletin, sinensetin, wogonin	Parsley, celery, skin of citrus fruit
Phenolic Acids		
Benzoic acid derivative	Gallic acid, vanillic, syringic, hydroxybenzoic	Tea, strawberries, raspberries, blackberries, black radish, onions
Cinnamic acid derivative	p-Coumaric, caffeic, ferulic, sinapic acids, vanillin, syringaldehyde, p-hydroxybenzaldehyde	Blueberries, kiwis, plums, cherries, apples, cereal grains, coffee
Lignan	Secoisolariciresinol	Linseed, lentils, cereals, garlic, asparagus, carrots, pears, prunes
Stilbene	Resveratrol	Grapes, red wine
Saponin	Ginsenoside	Ginseng root
Other polyphenols	Curcumin	Turmeric

Phenolics, and flavanoids in particular, are ubiquitous in plants and therefore represent an important component of a normal human diet. Epidemiological studies have suggested associations between consumption of phenolic-rich foods or beverages and various diseases, such as stroke, cardiovascular disease, and cancer [24] and neurologic disorders such as dementia/AD [25-26]. Naturally, multiple phenolic compounds coexist in foods. Many investigations utilizing animal models have demonstrated, for instance, that berry extracts with high levels of anthocyanins or other polyphenols can reverse brain insult- and age-related cognitive decrements in rodents and that the actives can cross the blood brain barrier [27]. Similarly, in healthy humans, complex mixtures of cocoa-flavanols have been shown to increase peripheral vaso-dilation and cerebral blood flow during task performance, as indexed by functional MRI [28], and improve performance on cognitively demanding tasks [29]. However, the majority of the research in this area is concentrated on the effects of single molecules and the following includes a review of evidence surrounding the 3 most promising single molecule candidates. The chemical structure of curcumin, EGCG and resveratrol are shown in Figure 5.2.

Figure 5.2. Structures of phenolic compounds like Curcumin, Resveratrol and EEG.

Curcumin. Curcumin, a curcuminoid polyphenol responsible for the bright yellow color of the Indian spice turmeric (*Curcuma longa* L.), has been utilized for centuries within the Ayurvedic system of medicine for the treatment of a whole host of ailments, including inflammation [30]. Curcumin exerts varied and wide-ranging effects on molecular targets [31]. These include transcription factors such as NF2, a master regulator of the antioxidant response; the protein kinases, which are involved with the majority of cellular pathways, especially those involved with signal transduction; enzymes such as heme oxygenase 1, a stress response protein whose expression is upregulated after curcumin consumption and associated with neuroprotection [32]; invasion and angiogenesis biomarkers such as matrix metalloproteinase 9, which are associated, among numerous other activities, with tissue repair; and inflammatory mediators such as NF- κ B and cytokines such as TNF α and IL-1 and IL-6 [33]. In animals, some of the physiological effects attributed to curcumin include activity against a range of neurologic diseases in animal models, including AD, multiple sclerosis, Parkinson's disease, age-associated neurodegeneration, schizophrenia and depression [34-39].

EGCG. A number of the catechin polyphenols that are abundant in tea (*Camellia sinensis* L.) are reputed to have pharmacologically active properties. The 4 main tea flavanols are: (-)-epigallocatechin, (-)-epicatechin, (-)-epicatechin-3-gallate, and EGCG, with EGCG generally thought to be the main and active component in green tea. The potentially neuroprotective effects of EGCG include direct effects seen *in vitro* in metal chelation [40], as an anti-inflammatory agent [41], and in the reduction of amyloid- β and amelioration of amyloid- β induced neurotoxicity [42-43], with these neuroprotectant properties being in part mediated via the activation of cell survival genes and modulation of protein-kinase c signaling [40]. EGCG has also been shown to facilitate cholinergic transmission [44], enhance neurite outgrowth [45], and modulate cerebral blood flow parameters in healthy humans. *In vivo* evidence from animal models suggests neuroprotective properties in the face of AD [46-48] and Parkinson's disease [49] and following ischemia/reperfusion injury [50-51]. Long-term administration of green tea catechins (63% EGCG) has also been shown to improve cognitive performance and increase antioxidant capacity in normal rats [52] and rats infused with

amyloid- β [53]. EGCG was also found to significantly increase the lifespan of *Candida elegans*, although, interestingly, this was observed only during situations of increased heat and oxidative stress [54].

This might suggest that the life-extending (and perhaps other) effects of EGCG are due to antioxidant actions and an upregulation of stress resistance-related proteins such as heme oxygenase 1. Indeed, pretreatment of cells with EGCG is associated with an increase in levels of heme oxygenase 1 [55]. Despite the relatively small number of investigations into the neuroprotective properties of EGCG in humans, epidemiological evidence reports that higher consumption of tea/green tea is associated with a reduced risk of neurodegenerative disorders [56] and a lower prevalence of cognitive impairment. Future research should therefore consider both acutely and chronically supplementing green tea catechins to young, healthy participants as well as to those with cognitive senescence.

Resveratrol. The phytoalexin resveratrol (3, 4, 5 trihydroxystilbene) is produced within a range of edible plants in response to tissue damage and environmental stressors such as fungal and viral attack [57-58]. Consumption of resveratrol is associated with numerous protective health benefits in mammals, including increased longevity [59], antiinflammatory [60] and antiviral properties [61], and protection against cancer and tumorigenesis [62], cardiovascular disease [63], and atherosclerosis [64]. With regards to these latter 2 effects, resveratrol has been associated with the French paradox, whereby the consumption of red wine in some cultures has been suggested to contribute to a relatively low incidence of coronary heart disease despite a diet high in saturated fats [65-66]. Potential neuroprotective mechanisms of action include improving blood flow and perfusion [67] and the promotion of antioxidant defenses [68], which *in vivo* are likely to be as a result of resveratrol bolstering the bodies' own endogenous antioxidant defenses via upregulation of a host of antioxidant enzymes [69]. This may be partly a consequence of activation of the Nrf2 transcription factor, which plays a central role in the regulation of cellular redox status [70] and modulation of the protein kinases, which were observed to be involved with neuroprotection against amyloid- β -induced toxicity [71] *in vitro* [72] and *in vivo*, specifically in the hippocampus [73]. *In vivo*, oral administration has also been shown to diminish amyloid- β plaque formation in a region-specific manner in a transgenic mouse model [74]. Resveratrol was shown to provide protection from hypoxic and toxic insults in *in vitro* and *in vivo* experiments of endothelial and primary neuronal cultures (Table 5.2 and Table 5.3).

An expanding body of preclinical evidence suggests that resveratrol has the potential to impact a variety of human diseases. In order to translate encouraging experimental findings into human benefits, more research is needed on the complementary nature of *in vivo* and *in vitro* studies. *In vitro* studies permit rapid screening for interactions, which are likely to be clinically meaningful, and can also be used to evaluate mechanism of action after animal studies; *in vivo* studies confirm or reject the *in vitro* prediction. The vast majority of the published studies on resveratrol performed with *in vitro* or *in vivo* models highlight its potential applications in the prevention and treatment of various disorders through multiple mechanisms of action that may be related to its health benefits [75].

Resveratrol (3,5,4'-trihydroxystilbene) is a polyphenolic phytoalexin that occurs naturally in various edible plants [76]. Resveratrol is composed of two aromatic rings connected by a styrene double bond that allows it to exist in *trans*- and *cis*-isomers [77-78]-*trans*-Resveratrol is the preferred steric form and is recognized to have greater biologic activity if it is protected from high pH and UV light. Resveratrol has been identified as a potential factor responsible

for the French paradox [79-80]. In recent years, this molecule has received considerable attention for its anti-inflammatory, anti-apoptotic, anti-oxidative, anti-diabetic, anti-viral and cardio-protective properties [81-84].

Table 5.2. *In Vitro* Examples of Resveratrol in Neuroprotection

In vitro model	Resveratrol treatment	Stress/exposure	Study outcomes	References
Mice primary neuronal cultures	1, 3, or 30 μ M post-treatment for 24 h	OGD for 3 h	neuroprotection	[85]
Rat primary neuronal cultures	0.1, 1.0, or 10.0 μ M pretreatment for 24 h	OGD for 2 h	antiapoptotic	[86]
Rat cortical mixed glial cells	5, 10, 25, 50, or 100 μ M post-treatment for 16 h	OGD for 0.5, 2, or 4 h	neuroprotection and anti-inflammation	[87]
Rat endothelial cultures	100 nM to 10 μ M pretreatment for 3 days	OGD for 3.5 h	antioxidation	[88]
HT22 cells	10 μ M cotreatment for 24 h	4 mM glutamate for 24 h	direct and indirect antioxidation	[89]
PC12 cells	25 μ M pretreatment	50 μ M DTPA-Fe ²⁺ and 1 mM t-BuOOH for 2 h	antioxidation and antimutagenic	[90]
	15 μ M pretreatment for 6 h	H ₂ O ₂ for 12 h	antioxidation, anti-inflammation, anticarcinogenic	[91]
	5, 10, or 25 μ M pre- or post-treatment for 24 h	OGD for 6 h	neuroprotection	[92]
PC12 cells cocultured with BV microglia	100 μ M pretreatment for 3 h	LPS 1 μ g/mL for 24 h	antiapoptotic	[93]
Organotypic hippocampal slice cultures	10, 25, or 50 μ M pretreatment for 24 h	OGD for 1 h	neuroprotection	[94]
Neonatal rat midbrain slice cultures	10–100 μ M	sodium azide, thrombin or N-methyl-N-nitrosourea	neuroprotection	[95]

Table 5.3. *In Vivo* Examples of Resveratrol in Neuroprotection

In vivo model	Resveratrol treatment (route)	Dosing schedule	Study outcomes	References
Neonatal mice (H-I)	0.002, 0.02, or 0.2 mg/kg (ip)	3 different time points: 24 h before H-I; 10 min before H-I; 5 h after H-I	reduced tissue loss	[97]
Mouse MCAO	50 mg/kg (iv)	daily for 7 days	neuroprotection	[98]
	20 mg/kg (po)	acute, 2 h before stroke; chronic, daily for 7 days	neuroprotection from free-radical or excitotoxicity damage	[100]
	50 mg/kg (po)	daily for 7 days before stroke	reduced neuronal injury	[100]
	0.068, 0.68, or 6.8 mg/kg (ip)	single dose after stroke	neuroprotection with extended therapeutic window	[85]
	1, 2.5, or 5 mg/kg (iv)	3 or 6 h after stroke	neuroprotection and anti-inflammation	[101]
Rat MCAO	20 mg/kg (po)	for 3 days after stroke	neuroprotection	[102]
	30 mg/kg (ip)	first dose 3 h post-stroke and subsequent daily dose for 4 days	neuroprotection and antiapoptotic	[103]
	30 mg/kg (ip)	pretreated for 7 days	neuroprotection	[104]
	0.001 or 0.003 mg/kg (iv)	single dose 15 min before ischemia	vasodilation, antioxidation	[105]
	0.001 or 0.003 mg/kg (iv)	single dose at reperfusion	antioxidation	[106]
	0.1 mg/kg (iv)	twice, 15 min preocclusion and at the time of reperfusion (2 h postocclusion)	reduced infarct volume and edema, improved neurological deficits, anatomical and functional preservation	[107]
	15 or 30 mg/kg (ip)	pretreated for 7 days and 30 min before MCAO	reduced neurological score, infarct volume, and brain water content	[108]
	20 mg/kg (ip)	pretreated for 21 days	decreased infarct volume and antioxidation	[109]
	oxy-resveratrol, 10 or 20 mg/kg (ip)	twice, immediately after MCAO and at reperfusion	reduced infarct volume, improved neurological deficits	[110]
Rat SAH	10 mg/kg (iv)	daily for 3 days after hemorrhage	neuroprotection, antioxidation and vasodilation	[111]
Rat global ischemia	10, 50, or 100 mg/kg (ip)	pretreated for 48 h	neuroprotection	[112]
Rat recurrent ischemic stroke	25 mg/kg (po)	three doses of resveratrol given daily after stroke	neuro- and cardio-protection	[113]
GerB BCCAO	30 mg/kg (ip)	twice, during and shortly after CCA occlusion	decreased delayed neuronal cell death and glial cell activation, can cross blood-brain barrier	[114]

Figure 5.3. Potential targets associated with anti-stroke activity of resveratrol.

Resveratrol exhibits therapeutic response against stroke by preventing brain infarct, edema, mitochondrial dysfunction and cognitive and motor impairment. Furthermore, it diminishes nitrosative, oxidative, and DNA damage, which leads to preclusion of apoptosis and neuroinflammation.

Here, in this section we discuss the findings on the neuroprotective potential of resveratrol from *in vitro* and *in vivo* stroke experimental models and multiple mechanisms of action that may be related to its health benefits through either direct or indirect antiapoptotic, anti-inflammatory, and antioxidative routes (Figure 5.3). This summary also helps to clarify the relationships among *in vitro* potency with respect to mechanism of action, drug concentration, and *in vivo* efficacy in clinical and preclinical findings.

Resveratrol, a natural stilbene present at relatively high concentrations in grape skin and seeds and red wine, is known for its purported antioxidant activity in the vascular and nervous systems. In contrast to its direct antioxidant role within the central nervous system, recent research supports a protective mechanism through increasing endogenous cellular antioxidant defenses, which triggers a cascade of parallel neuro-protective pathways.

A growing body of *in vitro* and *in vivo* evidence indicates that resveratrol acts through multiple pathways and reduces ischemic damage in vital organs, such as the heart and the brain, in various rodent models. Most of the protective biological actions of resveratrol have been associated with its anti-oxidative, anti-inflammatory, and anti-apoptotic properties and other indirect pathways see figure 5.3.

PROTECTIVE ROLE OF POLYPHENOLS IN NEURONAL ISCHEMIC INJURY

A significant interest on the protective effects of polyphenols has principally been because of their antioxidant properties. Phenolic antioxidants have been shown to inhibit the oxidation of lipids and other molecules and protect against free radicals [114]. Oxidative stress is a key event in the pathogenesis of cerebral ischemia. Overproduction of ROS during ischemia and/or ischemia/reperfusion can damage lipids, proteins, and nucleic acids, thereby inducing apoptosis or necrosis. Increasing evidence supports the hypothesis that plant polyphenols provide protection against neurodegenerative changes associated with cerebral ischemia [115].

Whether regional differences exist in the brain in the protective effects of polyphenols in ischemic injury is not clear. Most studies have reported the protective effects of polyphenols in the hippocampal and cerebral cortex regions in ischemia. Inanami et al. [116] observed a dose-dependent protection against hippocampal neuronal death in ischemia in gerbils after ad libitum oral administration of catechin in the drinking water for 2 weeks. Epigallocatechin-3-gallate (EGCG) also protected the hippocampal region in gerbils after transient global ischemia [117] and neuronal damage in a rat model of transient focal cerebral ischemia [118]. EGCG (50 mg/kg; intraperitoneal) was effective even when it was administered 3 hr after the ischemic insult in gerbils [119]. Hong et al. used green tea extract in the drinking water ad libitum for 3 weeks before ischemia in gerbils. This treatment reduced the infarct volume, the number of apoptotic cells, and lipid peroxidation, and inhibited the ischemia-induced hyperactivity [120]. In another focal ischemia model using middle cerebral artery occlusion (MCAO) in rats, the protective effects of resveratrol were shown with pretreatment for 21 days (20 mg/kg intraperitoneally per day). The treatment reduced the infarct volume, prevented motor impairment, and inhibited lipid peroxidation [121]. A single dose of resveratrol (20 mg/kg) given orally 1 hr before permanent middle cerebral artery ligation in mice did not protect against ischemic damage. However, when given daily for 3 days before ischemia, resveratrol significantly reduced the infarct size. In another study, effects of resveratrol on transient global cerebral ischemic injury were examined in gerbils [122]. Resveratrol (30 mg/kg given intraperitoneally per day) was injected either during or shortly after common carotid artery ligation and 24 hr later. Resveratrol significantly decreased neuronal death in the hippocampus and also inhibited glial cell activation. Nanocapsule encapsulated quercetin treatment resulted in significant protection to endogenous antioxidant enzymes against ischemia induced oxidative damage in neuronal cells of young and old rats [123]. Not many studies have reported the effects of polyphenols in the striatum except that by Shukla et al. [124] who saw a significant inhibition in lipid peroxidation and an increase in superoxide dismutase (SOD) activity in corpus striatum in rats pre-treated with curcumin prior to MCAO.

Some studies have examined the protective effects of polyphenols in the striatum but not in ischemic injury. For instance, GTE and EGCG were effective in preventing the depletion in striatal dopamine and tyrosine hydroxylase protein levels in a mouse model of Parkinson's disease [125]. It appears from these studies that protective effects of polyphenols would potentially be observed in the striatal region if assessed in ischemic injury. As mentioned above, cerebral cortex is another region where ischemic injury has been observed. Shukla et

al. [124] reported an antioxidant effect of curcumin in the cortex of rats subjected to MCAO. Red wine polyphenol compounds also protected against oxidative stress in rats following MCAO/reperfusion [126]. Similarly, resveratrol significantly attenuated neuronal death in and decreased the generation of ROS, lipid peroxidation and nitric oxide (NO) content in the cortex of rats subjected to transient global ischemia [127]. 2,3,5,4'-tetrahydroxystilbene- 2-O-beta-D-glucoside (TSG), an active component of the rhizome extract from *Polygonum multiflorum*, significantly reduced infarct volume in the cortex following MCAO [128]. Taken together, these studies indicate that polyphenols either exert or have the potential to exert neuroprotective effects in various regions in the brain that are vulnerable to ischemic injury. While the precise dose required to achieve a neuroprotective effect in cerebral ischemia is not clear and may vary with individual polyphenols,

Sutherland et al. [118] have reviewed the effects of green tea catechins including the safety and efficacy of such catechins. One mechanism underlying the neuroprotective effect of polyphenols is possibly through its effects on reducing the levels of apoptotic markers. Pomegranate polyphenols and resveratrol protect neonatal mouse brain from ischemic injury by reducing caspase-3 and calpain activation [129]. In neonatal rats, amentoflavone blocked the activation of caspase-3 and the proteolytic cleavage of its substrates following hypoxic-ischemic injury [130]. Pomegranate juice also diminished caspase-3 activation in the hippocampus and cortex of the neonatal brain against a hypoxic-ischemic insult through supplementation of the maternal diet with pomegranate juice [131]. Mangiferin and morin, two antioxidant polyphenols, are neuroprotective in both *in vitro* and *in vivo* models of ischemia possibly by reducing Ca^{2+} influx and decreasing caspase-3 [132]. A subsequent *in vitro* study by Campos-Esparza et al. [133] demonstrated that mangiferin and morin reduced the formation of ROS and restored the mitochondrial membrane potential following excitotoxic stress, which is a major component of ischemic injury. Further, these polyphenols also reduced the glutamate-induced activation of calpains, normalized the level of cytosolic Bax and inhibited the release of AIF from mitochondria. These actions of mangiferin and morin could well be part of their profile in an *in vivo* model of ischemic injury. EGCG, a green tea polyphenol, reduced up-regulation of MMP-9 activity and neuronal damage following transient focal cerebral ischemia in C57BL/6 mice [134]. MMP-9 downregulation by resveratrol was also observed in an *in vitro* model of neuronal ischemic injury [135]. 5,7,3',4',5'-pentahydroxy dihydroflavanol-3-O-(2"-Ogalloyl)-beta-d-glucopyranoside (AP1), a polyphenolic compound isolated from *Anogeissus pendula* Edgew (an arid forest tree), was effective in reducing apoptotic cells in rat brain following transient focal cerebral ischemia [136]. The effect of TSG in protecting rat brain from MCAO is by increasing the anti-apoptotic Bcl-2 proteins.

Curcumin, a potent polyphenol antioxidant enriched in turmeric, reduced cytochrome c release and subsequent caspase-3 activation following global cerebral ischemia in Mongolian gerbils [137]. While the aforementioned studies have demonstrated a decrease in caspase-3 levels in the presence of polyphenols, it is unclear whether polyphenols act directly on caspase-3 or whether they act on upstream caspases that are precursors to caspase-3. Alternatively, such polyphenols could also be activating inhibitor of apoptosis (IAP) which would then inhibit caspase-3 activation. In addition, effects of polyphenols may also involve protecting mitochondrial dysfunction in ischemic injury as seen *in vitro* [138]. Preventing the decline in mitochondrial membrane potential following ischemic injury may subsequently confer protection against apoptotic cell death. In addition, resveratrol can induce

neuroprotection by increasing mitochondrial ATP synthesis efficiency in rat brain following ischemia [139]. While these studies highlight the potential neuroprotective mechanisms by which polyphenols attenuate cell death in ischemia, their antioxidant and anti-inflammatory effects may also contribute to their ability to reduce cell swelling and/or brain edema which can be deleterious to neuronal and glial functioning.

ROLE OF POLYPHENOLS IN ATTENUATING OXIDATIVE STRESS AND MITOCHONDRIAL DYSFUNCTION

Oxidative stress is a key component of ischemic injury including cell swelling and brain edema and polyphenols, due to their antioxidant properties, would be postulated to attenuate such injury. Reports on the beneficial effects of polyphenols on brain edema in ischemia are scarce. Resveratrol has been reported to reduce brain edema in rats following MCAO [140]. Lee et al. has reported a protective effect of green tea polyphenol EGCG against neuronal damage and brain edema after unilateral cerebral ischemia in gerbils. AP1, a polyphenolic compound, also reduced brain edema in rats after transient focal ischemia [141]. Recently the protective effects of polyphenols from green tea as well as cinnamon on glial swelling in cultures following ischemia-like injury has been reported [142]. Myricetin and quercetin also attenuated cell swelling following oxygen-glucose deprivation in C6 cultures [143]. While in cell culture studies polyphenols reduced cell swelling, it is possible that the reduction in cell swelling was not due to the antioxidant effects of polyphenols.

An increase in intracellular calcium is a key feature of ischemic injury [144]. Further, an increase in $[Ca^{2+}]_i$ can induce cell swelling as demonstrated in lactic acidosis-induced glial swelling [145] and in hypo-osmotic swelling in cultured astrocytes [146]. It has been demonstrated that quercetin and myricetin both attenuate OGD-induced increase in $[Ca^{2+}]_i$. Also, such blockade of the rise in $[Ca^{2+}]_i$ by blockers of the L-type calcium channel as well as modulation of $[Ca^{2+}]_i$ through BAPTA, a calcium chelator, reduces cell swelling in C6 glial cultures [147]. Other studies have also shown a decrease in $[Ca^{2+}]_i$ following administration of polyphenols. Quercetin attenuated the H_2O_2 -induced calcium dysregulation in PC12 cells [148]. Quercetin, catechin, and resveratrol also inhibited cardiac voltage gated sodium channel in rat cultured myocytes, but had no effect on the reverse mode NCX, the Na^+ / Ca^{2+} exchanger [149]. Apple condensed tannins inhibit the increase in intracellular free Ca^{2+} concentration in RBL-2H3 cells induced by antigen stimulation [150]. EGCG reduces the glutamate-induced $[Ca^{2+}]_i$ increase by attenuating ionotropic Ca^{2+} influx in PC12 cells [151]. Nevertheless, these studies indicate that polyphenols have the potential to modulate calcium channels that are involved in cell volume regulation, but their role in attenuating glial swelling/cytotoxic edema in ischemia needs to be further elucidated.

Mitochondrial dysfunction is an important characteristic of ischemia. The mitochondrial permeability transition (mPT) has been implicated as one mechanism, or at least part of the mechanistic pathway, for cell swelling in cultured astrocytes following ammonia toxicity or TBI as well as in brain sections in ischemia [152]. Despite these studies, the role of the mPT in cell swelling is not clear. Recently it has been demonstrated that the attenuation of cell swelling and the prevention of the decline in mitochondrial inner membrane potential ($\Delta\Psi_m$) by immunosuppressants, cyclosporin A (CsA), but not FK506, are consistent with the role of

the mPT mediating such events. Similar to CsA, CPE, and green tea polyphenols, also significantly prevented OGD-induced cell swelling and the decline in $\Delta\Psi_m$ in C6 glioma indicating that one mechanism by which CPE and GTE exert their protective effects is possibly by blocking the mPT. Interestingly, quercetin significantly attenuated cell swelling in C6 glial cells following OGD but did not block the dissipation of the $\Delta\Psi_m$ [147] indicating that other factors, besides the mPT, mediate the development of cell swelling in ischemic injury. It is also possible that preventing the induction of the mPT may be sufficient in some cases but may not be always necessary.

An increase in inflammatory markers has been associated with brain edema [153] and could potentially cause damage to the BBB [154]. A disruption of the BBB is observed in vasogenic brain edema. A key characteristic of polyphenols is their anti-inflammatory property [155] and anti-inflammatory effects of polyphenols have been reported in cerebral ischemia [156]. Inflammatory molecules can damage mitochondrial function. For instance, exposure of rat astrocyte cultures to interferon $-\gamma$, in the presence or absence of LPS, can increase NO production which can subsequently damage the mitochondrial respiratory chain complex function. Studies that investigated the role of polyphenols on BBB function in ischemia are scarce except that reported by Zhang et al. [157] which examined the effects of green tea polyphenols on BBB permeability following MCAO in rats. They report a decrease in BBB permeability in the ischemic region in the presence of green tea and a concomitant decrease in levels of caveolin-1, a protein involved in BBB functioning and permeability. Wang et al. and Lee et al. report a reduction in water content in the brains of animals following ischemia with resveratrol and EGCG respectively, but it is not clear if the edema that was measured was of the vasogenic or cytotoxic type. Likewise AP1, a polyphenolic compound, also reduced brain edema in rats following MCAO but the type of edema assessed is not clear. A reduction in BBB damage and water content in the brain following cerebral ischemia in rats was reported with curcumin [158]. Curcumin also decreased brain edema in rats following MCAO [159] but as with some other studies the type of edema examined is not clear. In a rat thromboembolic stroke model, curcumin reduced brain edema [160] most likely of vasogenic type.

In addition, curcumin was reported to significantly lower oxidized proteins and interleukin-1 β , a pro-inflammatory cytokine, elevated in the brains of AD transgenic mice [161]. IL-1 receptor 1 (IL-1R1)-null mice when subjected to hypoxia-ischemia showed reduced cytotoxic and vasogenic edema when compared to wild-type mice [162]. Taken together it is conceivable that curcumin could attenuate vasogenic edema following ischemia. Further, anti-inflammatory properties of polyphenols have been reported in other stresses and this knowledge can be applied to vasogenic edema in ischemia. Polyphenols found in cinnamon also have anti-inflammatory effects *in vitro* [163]. A reduction in TNF- α , an inflammatory cytokine, has been reported for green tea polyphenols [164] as well as dried plum polyphenols [165] and TNF- α is one agent that increases endothelial permeability in vasogenic edema. Also, increases in intercellular adhesion molecule (ICAM-1) and myeloperoxidases in rodent lung injury are attenuated by green tea polyphenols [166]. In addition, anti-cyclooxygenase 2 effects of resveratrol [167], as well as anti-MMP9 effects of resveratrol [168] and other polyphenols have been demonstrated. The importance of inflammation in vasogenic edema, taken together with the anti-inflammatory effects of polyphenols, indicates that the polyphenols may play a protective role in reducing vasogenic brain edema in ischemia.

OXIDATIVE STRESS AND MITOCHONDRIAL DYSFUNCTION ARE KEY FEATURES OF CEREBRAL ISCHEMIA

Oxidative stress and mitochondrial dysfunction are key features of cerebral ischemia that affect neuronal viability after ischemia. In addition, these factors also affect brain edema which is a major consequence of ischemia and can be fatal if not resolved. Edema can further aggravate neuronal injury by affecting cerebral perfusion. Currently, there are few remedial agents to effectively reduce neuronal death or brain edema not only in ischemia but also in other neural injuries including traumatic brain injury. The potential for the use of polyphenols in the preventing cell loss or damage and edema in cerebral ischemic injury is tremendous. However, the cellular and molecular actions of polyphenols involved in neuroprotection have to be elucidated further. Given the large proportion of the population affected by stroke and traumatic brain injury, and with few strategies to effectively attenuate brain edema and associated neural damage, it is important to determine the potential beneficial effects of dietary polyphenols in the prevention and alleviation of such damaging effects.

ROLE OF POLYPHENOLS IN PREVENTING NEUROINFLAMMATION

Although neuroinflammation plays a critical role in brain host defence, it also contributes to the underlying neuronal loss in neurodegenerative disorders and to damages associated with cerebral ischemia [169]. Neuroinflammation is “driven” by activated resident glial cells (astrocytes and microglia) which result in invasion of circulating immune cells and the production of proinflammatory cytokines (TNF- α , IL-1 β , and IL-6), nitric oxide (NO), prostaglandin E2, chemokines, and reactive oxygen species (ROS). Amongst the numerous factors released by activated glial cells, excessive NO• production has been reported to induce neuronal cell death by damaging the mitochondrial electron transport chain function in neurons [170] therefore resulting in neuronal ATP synthesis disruption and in increased generation of ROS [171]. Furthermore, NADPH oxidase activation, an important event in activated microglia-induced neurotoxicity, has also been suggested to mediate both superoxide (O₂⁻) production and to release proinflammatory molecules such as TNF- α [314]. NO• produced in microglia or astrocytes may react with O₂⁻, produced by NADPH oxidase to generate the neurotoxic peroxynitrite radical (ONOO-) [172]. ONOO- has been observed to inhibit mitochondrial respiration, induce caspase-dependent neuronal apoptosis, and to induce glutamate release resulting in excitotoxicity and neuronal death [173]. Additionally, glial cytokine production may also play a deleterious role in neurodegenerative diseases by binding to specific cell surface receptors expressed in neurons and activating apoptotic pathways.

There has been much interest in the development of new drugs capable of preventing neuroinflammatory-mediated brain injury. Emerging evidence suggests that dietary polyphenols may exert neuroprotective effects by suppressing the activation of microglia, which mediates inflammatory processes in the CNS. Although rather complex, the main anti-inflammatory properties of polyphenols include: (1) an inhibitory role on the release of cytokines, such as IL-1 β and TNF- α , from activated glia; (2) an inhibitory action against iNOS induction and subsequent nitric oxide production in response to glial activation; (3) an

ability to inhibit the activation of NADPH oxidase and subsequent ROS generation in activated glia; (4) a capacity to downregulate the activity of proinflammatory transcription factors such as NF- κ B through their influences of a number of glial and neuronal signaling pathways, such as MAPK cascade (discussed in details below) [174-175]. For example, the commonly consumed flavonol quercetin has been reported to inhibit neuroinflammation by attenuating nitric oxide production and iNOS gene expression in microglia [176] and by preventing inflammatory cytokine production, thus preventing neuronal injury [177-178]. However, one of the major physiological metabolites of quercetin, quercetin-3_-sulfate, failed to demonstrate any anti-inflammatory action. Nevertheless, these studies have employed quercetin concentrations (10–50 μ M) much higher than of those found in plasma after ingestion.

Figure 5.4. Mechanisms underlying the biological effects of polyphenols. Polyphenols and their *in vivo* metabolites activate cellular stressresponse pathways resulting in the upregulation of neuroprotective genes. For example, both PKC and ERK can activate the nuclear factor erythroid 2-related factor 2 (Nrf2). Nrf2 then translocates to the nucleus and binds to the antioxidant response element (ARE) in genes that encode cytoprotective proteins such as antioxidant enzymes (AOE) and phase 2 (Ph2) enzymes. The transcription factor cAMP-responseelement-binding protein (CREB) is also activated by ERK, which induces the expression of brain-derived neurotrophic factor (BDNF), a mediator of neurohormesis. In addition, polyphenols can also regulate the transcription factor NF- κ B, which can mediate adaptive cellular stress responses by reducing the expression of inflammatory cytokines. Activated SIRT1 may also inhibit NF- κ B and so can reduce the cellular stress response. Another important pathway activated bymetabolic and oxidative stress involves transcription factors of the forkhead (FoxO) family, which modulate genes that encode antioxidant enzymes and other stress-response proteins.

In contrast to this, epicatechin and catechin (10–300 nM) were observed to inhibit TNF- α release but not iNOS expression or nitric oxide production in primary glial cells [179] suggesting that flavanols at physiologically relevant concentrations may hold the potential to exert anti-inflammatory effects in the central nervous system. Polyphenols present in blueberry have also been reported to inhibit NO $\bullet$, IL-1 β and TNF- α production in activated microglia cells [180], and the flavanone naringenin was observed to be highly effective in reducing LPS/IFN- γ -induced glial cell activation [179]. Dietary polyphenols are also potent inhibitors of NADPH oxidase activity *in vitro*. A study comparing 45 polyphenolic compounds indicated that whilst both the flavanols (+)-catechin and (–)-epicatechin failed to inhibit NADPH oxidase, their relevant methylated metabolites exhibited strong NADPH oxidase inhibition through an apocynin-like mechanism [181]. Interestingly, other apocynin-like phenolic compounds, such as, ferulic acid, homovanillin alcohol, caffeic acid, tyrosol, and vanillic acid were also observed to inhibit NADPH oxidase activity, therefore indicating that smaller polyphenols, more structurally related to some colonic metabolites, may also serve as novel therapeutic agents in neuroinflammation (Figure 5.4).

There is also data which shows encouraging positive effects of polyphenols in animal and *in vitro* models relevant to multiple sclerosis (MS), a chronic debilitating disease which is characterised by demyelination, progressive irreversible axonal damage and inflammation [182]. For example, EGCG delivered orally reduces symptom severity in the autoimmune encephalomyelitis model of relapsing remitting MS by reducing inflammation and increasing neuroprotection [183]. Quercetin has also been reported to be effective in the Experimental Autoimmune Encephalomyelitis (EAE) mouse model, and reduces T-cell proliferation *in vitro* at concentrations exceeding 10 μ M [184]. Micromolar concentrations of luteolin, apigenin, fisetin, and quercetin (but not morin or hesperetin) were reported to suppress the production of the cytokine interferon-gamma (IFN γ) from lymph-node-derived T cells but, paradoxically, worsen clinical severity in the EAE model. More recently, resveratrol protection against EAE was associated with rises in IL-17/IL-10 and with repressed macrophage IL-6 and IL-12/23 p40 expression [185]. Thus, the studies to date show promising proof of concept of beneficial effects of polyphenols in suppressing immune and inflammatory responses in models of MS.

NEUROPROTECTION BY POLYPHENOLS IN HYPOXIC-ISCHEMIC INJURY IN NEONATES

Dietary supplementation with foods rich in polyphenols—pomegranates, blueberries, green tea, and apple juice—has been shown to provide neuroprotection in animal models of focal brain ischemia, of periventricular white matter injury, and of Alzheimer's disease [186–189]. Polyphenols have been found to possess antioxidant properties as well as to have effects on gene expression [190]. Specifically, one polyphenol, resveratrol, has been shown to increase activity of members of the sirtuin gene class, blunting p53 action and blocking apoptosis [191–192]. Recent studies indicate that among foods that contain polyphenols, juice extracted from the pomegranate has the highest concentration of measurable polyphenols [193–194]. The pharmacologic actions of pomegranate juice include antiatherosclerotic, antibacterial, and antiproliferative properties [195]. We recently found that when the

polyphenol rich pomegranate juice is consumed by the dam polyphenols from the juice are present in the pup and protected the pup against H-I brain injury [131]. Other studies have shown that the polyphenols caffeic acid, phenylethyl ester and amentoflavone are also protective against neonatal H-I brain injury [130]. To test the hypothesis that it is the polyphenols of pomegranate juice that are responsible for neuroprotection, we tested the effect of pomegranate polyphenol extract (PPE) in the neonatal H-I mouse model. Supplementation of PPE to the drinking water of pregnant and nursing dams resulted in significantly decreased H-I induced caspase-3 activation. This suggests that it is the polyphenols of the pomegranate juice that are responsible for the neuroprotection.

To further investigate the role of polyphenols in neonatal H-I we focused on the specific polyphenol resveratrol. This naturally occurring compound has been found to be neuroprotective in adult ischemia in rats when administered before the injury, but to our knowledge resveratrol has never been tested in neonatal H-I [196-198]. By examining a variety of different concentrations at several different time points we found that IP injection of resveratrol leads to decreased caspase-3 activation in the P7 mouse in a concentration and time dependent manner. At doses of 200 $\mu\text{g/kg}$ or greater, resveratrol leads to decreased caspase-3 activation but only when resveratrol is injected prior to the injury. In addition to decreasing the caspase-3 activation resveratrol also decreases the calpain activation following neonatal H-I, suggesting that it works as a generally neuroprotective agent and not just on the apoptotic pathway.

In addition to finding that resveratrol is protective in the neonatal mouse we also demonstrated that resveratrol protects the neonatal rat against H-I induced caspase-3 activation. Although the injury paradigm is similar in rats and mice there are several neuroprotective agents that have been found to work only in one species. Since resveratrol has been found to protect against stroke in neonatal rats and mice as well as in adults, it could potentially be considered for further investigations in humans. Interestingly, we did not find resveratrol to be protective in the rat when given after the injury. Since the apoptotic cell death in the rat starts much later in the rat than in the mouse, and several drugs have been shown to be protective in the rat when given after the insult, we thought that resveratrol might follow the same pattern. The fact that resveratrol does not protect when given after the injury suggests that it is acting through proximal mechanisms in the cell death pathway initiated by H-I. One pathway that may be involved in the effects of polyphenols is via activation of the sirtuins such as SIRT1.

Polyphenols such as resveratrol may have beneficial effects on health via their antioxidant properties, suppression of inflammatory pathways, or other pathways such as activation of the sirtuin pathway [199]. Included in the sirtuin family is SIRT1, a human protein deacetylase that promotes cell survival by mechanisms such as negatively regulating the p53 tumor suppressor [200], deacetylating the transcription factor FOXO3 [201], repressing PPAR γ signaling [202] and modulation of NF- κ B dependent transcription [203]. Modulation of these pathways may provide a means to protect the developing brain against neonatal H-I induced brain damage. Recent studies show that polyphenols, including resveratrol, increase cell survival via activation of SIRT1. Parker et al. found that increased *sir2* gene dosage or treatment with resveratrol in *C. elegans* blocked neuronal dysfunction and cell death induced by polyglutamine expansion. Suggesting that resveratrol may act through a similar pathway in mammals, resveratrol protected mammalian neuronal cell lines from mutant huntingtin-induced cell death and this effect was inhibited by sirtuin

inhibitors [204]. There is also evidence that resveratrol can block axonal degeneration via SIRT1 in the mammalian peripheral nervous system [205]. While increasing evidence suggests that resveratrol and other polyphenols are neuroprotective, whether their protective actions in the CNS *in vivo* are via SIRT1 has not been directly assessed. Determining the mechanism of protection of resveratrol, pomegranate polyphenols, and other polyphenols may lead to novel insights into both pathogenesis and treatment of neonatal H-I brain injury.

SUMMARY

The neuroprotective actions of dietary polyphenols involve a number of effects within the brain, including a potential to protect neurons against injury induced by neurotoxins, an ability to suppress neuroinflammation, and the potential to promote memory, learning, and cognitive function. While many of the mechanisms underpinning their beneficial effects remain to be elucidated, it has become clear that they in part involve decreases in oxidative/inflammatory stress signaling increases in protective signaling, and may also involve hormetic effects to protect neurons against oxidative and inflammatory stressors. Most of the dietary polyphenols that have been shown to be protective against age-related disease are all chemically reactive and nearly all are electrophilic.

Such chemical features renders these molecules capable of influencing the redox potential of their target cells and to modulate series of transcriptions factors that result in the activation of phase I and phase II metabolism genes. Nonetheless, much of the data obtained on their bioactivity derived from short-term basis *in vitro* or *in vivo* studies where the dose used was not of nutritional relevance. Although at the moment, the balance of evidence that does suggest that polyphenol effects contribute to the benefits of a high intake of fruits and vegetables, the extent of their contribution *in vivo*, and at physiological relevant concentrations remains uncertain. More work needs to be done to prove whether this class of compounds is most likely to result in health benefits and to determine their beneficial effects in slowly developing neurodegenerative disorders. In view of their multiple biological activities, the consumption of polyphenol-rich foods throughout life holds a potential to limit neurodegeneration and to prevent or reverse age-dependent deteriorations in cognitive performance. However, the therapeutic and pharmacological potential of these natural compounds still remains to be translated in humans in clinical conditions. Moreover, efficacy in RCT is also needed to support the relatively consistent epidemiological and mechanistic evidence. Despite this lack of efficacy data and the uncertainty of their effects *in vivo*, investigations into the absorption and metabolism of various polyphenols in humans indicate that there are common pathways for the metabolism of the majority of polyphenols, notably via their bacterial metabolism in the large intestine. Consequently, research on developing dietary polyphenols for applications in neurodegenerative disorders should prioritise investigations of smaller polar polyphenols for brain bioavailability and bioactivity. The challenge ahead therefore is to proceed cautiously until rigorous randomized controlled clinical trials have been undertaken to determine empirically whether polyphenols and/or their metabolites have efficacy in individuals affected by dementia and other neurodegenerative conditions.

In general, the literature on the efficacy of the herbal extracts and phytochemicals reviewed here in terms of improving aspects of human brain function is somewhat equivocal. Research on two alkaloids, caffeine and nicotine, is confounded by withdrawal effects and most of the remaining treatments have failed to progress beyond relatively small scale human studies. Indeed, in the case of the single molecule polyphenols (curcumin, resveratrol, EGCG), their huge and exponentially expanding literatures are singularly lacking in reports of relevant human intervention trials. Of the 3 treatments that have progressed to larger scale controlled trials and eventual meta-analyses, both GB and valerian are be devilled by methodological inconsistencies and inadequacies that make conclusions difficult to draw, with only St. John's Wort consistently demonstrating efficacy.

The phenolic compounds, particularly those like flavonoids that are ubiquitously consumed in plant-based foods, may then owe the balance of their CNS effects to the latter (but with notable exceptions in terms of hormonal effects and GABAergic effects). As well as the natural compatibility of molecules created by conserved stress signaling pathways common to both plants and humans, it is interesting to note that the induced antibacterial/fungal and viral effects of curcumin, EGCG, and resveratrol within the plant may be mirrored by a similar protection conferred after exposure to similar pathogens in human cells and animal models. Although an exact concurrence between the mechanisms of action across the taxa has not yet been established, Friedman has demonstrated that, *in vitro*, the antibacterial, antitoxin, antiviral, and antifungal properties of tea flavonoids were similar against all of the food-borne pathogens reviewed.

These mechanisms ostensibly involved either binding to the invader and inactivating it or perturbing the membrane structure of the pathogen and causing leakage, with both resulting in preventing or limiting the deleterious effects of the bacteria, toxin, or virus. With phenolic compounds in particular it is also interesting to note that humans are likely to have lost the ability to synthesize vitamins, which include several terpenoids and methylated phenols, because the ubiquity of these micronutrients in our diet made it more advantageous in evolutionary terms to sequester them from food rather than synthesize them *de novo*. The same argument has been made for all dietary antioxidants, including many non-vitamin phytochemicals, and this proposition could be extended to include the non-antioxidant properties of groups of phytochemicals that occurred as part of our natural ancestral diet. This would largely accommodate the phenolic compounds, and flavonoids in particular, that are ubiquitous in plant foods. It may be relevant that most phenolic compounds have low parent molecule bioavailability but still exhibit *in vivo* bioactive effects. The rapid process of metabolism that takes place in the body could be viewed as the body processing the molecules into, for instance, glucuronidated and sulfated metabolites to more effectively transport and utilize them, in much the same way that vitamins are processed into their active metabolites and derivatives following consumption.

The gradation in toxicity and ecological/CNS functions is also seen in the comparative levels of research attention paid to the chemical groups. The alkaloid group has benefitted from intense research for over 200 yrs and has provided a multitude of medicinal compounds with CNS activity. Interest in terpenes, on the other hand, has really only escalated in the last 25 yrs, during which time many advances have been made in terms of characterizing the constituents and activities of complex plant extracts that often have low toxicity, high bioavailability, and a multitude of potentially relevant physiological effects. Similarly, research into the health effects of phenolic compounds has only reached any considerable

level within only the last 15 yrs. In the case of alkaloids, they have proven particularly amenable to research and drug discovery because of their comparatively straightforward, single molecule modes of action. Evidence suggests that extracts with largely terpene or phenolic actives owe their effects to multifarious synergies between their component chemicals and this factor, along with an inability to reliably standardize extract constituents, has to date constrained their development and the clarity of the literature on their efficacy in humans.

The development of effective plant-based products for improving human brain function is constrained by a number of issues, including a need to definitively identify relevant active components and understand synergies within them and an inability to adequately standardize replicable extracts. It is evident that insects such as *Drosophila* and the honeybee are sensitive to modulation by a full range of pharmacological agents. However, insect behavioral studies have only involved secondary metabolites either as a consequence of using them as simple tools for the modulation of specific neurotransmitter targets or alternatively in insect models of drug abuse and addiction. It would seem appropriate that insect models could be utilized as simple, economical, time-efficient, and ethically acceptable tools for investigating the neuronal and behavioral consequences of individual phytochemicals and complex mixtures. It is also evident that there are many viable terpene/ phenolic extracts that may have beneficial effects on CNS function without the toxicity associated with psychoactive alkaloids. These may include complex chemical mixtures that attract symbiotic insects and potentially offer them cognitive benefits. However, many phytochemicals simply do not function effectively as single molecules and there are many examples of synergies within and between the chemical groups. Insect models may provide ideal starting points for disentangling these synergies prior to animal and human studies.

Many secondary metabolites are also expressed as a consequence of environmental stressors, and an increased understanding of the many and varied ecological roles of secondary metabolites should, in the future, make it practical to upregulate and standardize the levels of desired active components by introducing a variety of stressors such as herbivore attack, salinity, UV light, bacteria, or fungi in carefully controlled environments. Finally, the vast majority of the voluminous research relating to the topics briefly reviewed above is conducted in entirely discrete discipline “silos.” In terms of research relevant to brain function, the vast majority is basic laboratory research conducted *in vitro/vivo* in an entirely atheoretical context, often with parent molecules or chemical concentrations that are highly unlikely to be seen in the human brain. Asking the simple question of why plant chemicals modulate brain function can only serve to focus some of this huge research effort, with the integration of thoughts and concepts from a diverse range of disciplines, including molecular biology/biochemistry, plant science, zoology, entomology, pharmacology, medicine, neuroscience and psychology potentially offering an intellectual synergy that might move this area a step forward.

RECESSION, SKILLS AND NATIONAL DEVELOPMENT: THE SOUTH AFRICAN CASE

Salim Akoojee*

University of the Witwatersrand, Johannesburg, South Africa.

ABSTRACT

When an entity's profitability is threatened, skills development initiatives are subjected to stress. This is not unusual in unusual times. In trying economic times, the firm-level skills development initiatives take second place as a result of the austerity measures either in place already or in preparation for its anticipated effects. But what happens to national development imperatives in these times? This chapter explores the impact of the 2008 global financial crisis on national and skills development in South Africa. It reports the results of a firm-level response to employability and skills development and juxtaposes this with the national level response to the crisis in the country. Using data gathered at the height of the crisis, it is contended that the responses by national government and at firm-level, while reacting to the immediate needs of the economy, did little to impact on the substantive equity imperatives to which the country strives. In light of the peculiar skills development challenges, much more could have been achieved in holding private companies accountable for equity in light of their call for assistance. The 'golden moment' offered by the crisis represented an opportunity lost in the pursuit of workplace transformation as the need for redress and equity becomes increasingly urgent in South Africa.

INTRODUCTION

When an entity's profitability is threatened, skills development initiatives are subjected to stress. This is not unusual in unusual times. In trying economic times, the firm-level skills development initiatives take second place as a result of the austerity measures in place or anticipated in the foreseeable future (see for instance Kluve, 2006; TUC, 2009). But what happens to national development imperatives in these times? This chapter explores the impact of the 2008 global financial crisis on skills development for a selection of South African companies in the manufacturing sector. It reports the results of a firm-level response to employability and skills development undertaken during the economic crisis in light of the peculiar skills development challenges facing the country. It is argued that while the peculiar context allows for reliance on the state in responding appropriately to the crisis, the impact of the recession on equity and transformation is likely to be muted. What was an opportunity afforded by the crisis to achieve more equitable outcomes, has been lost.

Countries have responded in various ways to the crisis. Some states have chosen to make education integral to their 'recovery plans' (Bray and Varghese, 2009, p. 2), while others, such as the BRIC (Brazil, Russia, India and China) countries, have made education a critical component of semi-protected budgets (Douglass 2010, p. 24). More importantly, national governments have gone out of their way to encourage firms to retain their staff and to stimulate skills development in an attempt to mitigate the worst social impacts of the crisis (OECD 2009, p. 30). According to the OECD, the investment in education and training not only makes displaced workers less vulnerable, it also contributes to national economic restructuring as displaced workers find new job opportunities and support this new national restructuring (OECD 2009, p. 10). Such measures are therefore aimed at sustainably protecting the most vulnerable from the full impact of economic meltdowns. There is, nevertheless, need for ever vigilant social support, protection and extension, where the education sector is threatened by declining national budgets (Barakat et al. 2010). As such the upside to the downturn is that it does provide scope for countries to reposition themselves in the skills arena and offers an opportunity to engage more meaningfully with the equity and access imperatives in their economies. Therefore, one of the key challenges in circumstances like these is to capitalize on the moment with a sustainable and integrated response. Clearly, a coordinated response requires the imperatives of displacement to be accompanied by a surge in national education funding. However, in a situation where declining national budgets offer little additional funds, more creative responses are called for to engage the crisis.

While a coordinated and integrated response might well have required both supply-side imperatives (state education and training entities) and demand-side constituents (public entities and private sector companies) to be locked into synergy, there has been a perceptible lack of any engagement between these elements. However, in the South African case, the lack of synergy was more pronounced as national development challenges become more serious.

This chapter argues that the call for state support by private sector companies presented an opportunity for the establishment of more equitable workplaces. Especially since those that were most likely to be most affected by the recession were beneficiaries of the broader transformation agenda. By exploring the key features of the policy response to the recession and company-level survey data on skills development practices and recruitment, it is suggested that an opportunity might well have been lost to effectively engage the transformational imperative in South Africa. While some jobs might have been saved, the

impact on workplace equity could have been much more deliberately advanced. An opportunity was, therefore, lost.

The chapter begins with an overview of national development challenges. This is followed by the impact of the recession on key features of the South African economy. The response of the South African government is then explored. The chapter closes with some critical insights regarding implications of the response to the recession on the need to advance the equity imperative necessary for national development.

NATIONAL DEVELOPMENT CHALLENGES IN SOUTH AFRICA

National development challenges have been profoundly shaped by South Africa's fractured past and are still associated with considerable race, class, and related issues linked to its colonial legacy. The concern with the inequity that still prevails is everywhere apparent.

The excessive social challenges which the country faces include inter alia high unemployment, inequity, crime, corruption, ineffective social structure and poor service delivery. They suggest that unless some serious review of the social democratic transition is undertaken, the success of the national transition is unlikely. Various national policy proposals have been identified to resolve these challenges in the post-apartheid era. These include the Reconstruction and Development Program (RDP) introduced at the time of the transition in 1994; the Growth, Employment and Redistribution Strategy (GEAR) introduced in 1996 which was replaced by the Accelerated and Shared Growth Initiative (AsgiSA) (see McGrath and Akoojee, 2007). The latest initiative is the National Growth Path (NGP), initiated in 2010, which accompanies the Human Resource Development Strategy (HRD-SA) in providing the basis for a human-centered growth path. The latter has been particularly useful in attempting to focus attention on the need for national development to have a peculiarly inclusive nature. The African National Congress (ANC), the ruling party, has been particularly sensitive to the prevailing concern of inequity and has, for instance, been vociferous about the need to ensure that the latest initiative succeeds: "We will also make sure that these projects lead to more inclusive growth by meeting the needs of new industries and historically excluded communities" (ANC, 2011).

The equity imperative in society as a whole, and in education, has been a key consideration of the policy arena. Given a historical legacy of poor education access at every level, there has been a pressing need to ensure that generally poor skills level, low standing in international social development measures and the unusually high poverty levels need special consideration in the national developmental context (Bhorat and Kanbur, 2006).

Inequity is especially endemic. South Africa is ranked amongst the most unequal countries in the world. The Gini coefficient for the country is currently at 0.578 (World Economic Forum, 2011) with significant racial disparities, which makes South Africa one of the most unequal countries in the world. The 2009 Development Indicators Report points out that the Gini coefficient reached 0.666 in 2008 and 0.679 in 2009 (Pressley, 2009).

Survey results also reflect the wide disparity in society. The Income and Expenditure Survey conducted in 2005/6 reported that while 10 per cent of the population earn more than 50 per cent of household income, the poorest 40 per cent of the population account for less than 7 per cent of this, with the poorest 20 per cent accounting for less than 1.5 per cent

(StatsSA, 2008). Although it has been pointed out that poverty had begun to decline between 2001 and 2005 (Woolard and Woolard, 2008), the reality that the problem is a result of structural factors that need deliberate and targeted response cannot be ignored.

Rampant inequity is also associated with an unusually high unemployment rate. Current unemployment on the outer end estimates is pegged at between 27 and 30 per cent nationally. Strict unemployment peaked in 2001 at 31 per cent. There was reported growth in ‘broad unemployment’, as it did finally make inroads into unemployment, falling to 23 per cent (NPC 2011, p. 10). The current unemployment in the broad definition is estimated at 25 per cent for the third quarter of 2011. The problem of youth unemployment is particularly disturbing. One report estimated that there are more than 2.8 million people, aged between 18 and 24, who are not in education, employment or training (referred to as NEETs) (Cloete, 2009).

Education and skills development capacity is also consistent with employment. It has been reported that the probability of gaining employment is significantly increased once a tertiary qualification is attained (Bhorat et al. 2010). Despite the fact that there are considerable demographic, institutional and program choice considerations that hinder the prospects of some of those that qualify, it is evident that social progress is unlikely to be achieved for many without significant advances in post-school education and training access (see for instance Akoojee and Nkomo, 2007). The need for the country to advance the social development agenda by effective and meaningful investment in education at all levels is abundantly clear.

The need to ensure that the country succeeds is evidenced by the establishment since 2009 of a specialist National Planning Commission tasked with the responsibility of ensuring that a systemic response to the challenges is both developed and monitored.

Figure 1. Nature of the development challenge in South Africa. Source: NPC 2011, p.7.

The diagnostic report of this commission, released early in 2011, identified the centrality of educational outcomes and its counterpart, unemployment, as a key feature of the challenge facing the country as the Figure 1 reproduced from this document shows.

The challenge of poor and ineffective education outcomes is central to other key developmental challenges including inter alia employment, corruption, structural economic inconsistencies (resource intensiveness and poor service delivery by public entities).

The nature of the national development challenges in South Africa is therefore considerable. Poverty, inequality and unemployment loom large in the national arena, with its associated skills deficits and shortages in key areas of the country.

RECESSION AND ITS IMPACTS: THE SOUTH AFRICAN STORY

Impact of the Crisis

The onset of the economic recession as a result of the sub-prime crisis in the United States resulted in considerable international consternation. The subsequent government interventions and bailouts of macro-capitalist institutions that followed had important implications for the skills and national development. Importantly, it halted economic growth which averaged between 5 and 7 per cent globally before the crisis. The global economic hemorrhaging as a result of the decline in trade led to significant job and income losses and resulted in considerable setback of social programs of most governments (Chitiga et al. 2010; Verick and Islam, 2010). According to estimates by the International Labor Organization (ILO), it was to lead to more than a million people losing their jobs, and in World Bank estimates, an additional 46 million people globally were pushed below the poverty line (quoted in Bray and Varghese, 2009). While developed countries have been quite significantly affected, developing countries, especially those dependent on commodity prices, have been under tremendous strain. The resultant declining trade flows led to falling remittances from developed nations and impacted negatively on their already steadily dwindling aid budgets.

South Africa, although initially cushioned from the recession, was not completely unaffected. It could be argued that in the period from November 2009 to February 2010, the most detrimental impacts were to some extent neutralized by the government spending on infrastructure in preparation for the impending FIFA Football World Cup. But the initial ripples of the world economic turmoil were already being felt. The country was, nevertheless, initially insulated from its most visible deleterious results. In addition to the infrastructural spending of the international sporting event in 2010, the relative cushioning of the economy as a result of the banking regulations introduced before appeared to have had some positive impacts. The National Credit Act of 2008 for instance softened rampant lending. On the flip side, this resulted in a degree of lethargy about a meaningful response to the crisis and its likely impact on South Africa. As Hein Marais points out, “... until well into 2009....South Africa’s political and business elites seemed to languish in a state of denial and were broadcasting predictions of another year of positive economic growth, even as credit markets around the world asphyxiated and global demand dissolved” (Marais, 2010).

By the end of 2009 and early 2010, the façade was cracking. As will be shown later in this chapter, not only did employment decline, the considerable increase in the numbers of discouraged workers during that time suggests that the country was not immune from the international shock wave. The period was accompanied by an increase of more than 900 000 displaced workers (DPRU, 2009). The sharp fall in demand of its export products together with a fall in prices of key export commodities and dwindling foreign investment resulted in some concern (Chitiga et al. 2010). The particularly impressive performance of the post-apartheid economy, which averaged GDP growth of 3.3% from 1995 to 2003, declined in the second quarter of 2009 when the country was reporting its first recession in 17 years. This was the wake-up call, which exposed the underbelly of a vulnerable economic state buttressed by expanded public work projects. Since the last quarter of 2008, the declining demand for mining products and reduced manufacturing (which accounted for 16% of GDP and 14% of the workforce) had already showed signs of faltering. When the cumulative job losses in South Africa amounted to more than a million by the third quarter of 2009 (DPRU, 2009; ILO, 2010), some serious attention had to be paid. It was not surprising that by the close of 2009, the official prognosis was that the country was in recession. Even at this point, there was some downplaying of the challenge by some analysts. Verick (2010, p. 16) for instance suggests that "...the impact of the global financial crisis on the South African labor market is more evident in terms of rising discouragement, rather than a surge in official unemployment". This ignores the particularly salient fact that 'discouraged' workers, although not reported as officially unemployed, are indeed not employed. Indeed, the difference between broad (31.2%) and narrow (24.5%) unemployment at the height of the recession (between the second quarter of 2008 and the third quarter of 2009) reflects an increase in discouraged workers. The rise in the number of discouraged individuals, from 1.08 million in the second quarter of 2008 to 1.63 million in the third quarter of 2009 (*ibid*) provides telling evidence of considerable increase in unemployment not reflected in official figures, and thus significantly understated. There had clearly been a hemorrhaging of employment during the period which could simply not be ignored. The recession has unsurprisingly expanded the already widening disparity between 'haves' and 'have nots' outlined in the previous section. This inequity, associated as it was with differences in race, gender, age and level of education, was considerably affected. Table 1 shows the impact of the recession on key labour market variables in the period 2008 and 2009.

If unemployment was serious before the recession, the post-recession situation was especially disturbing. The impact on key equity indicators was particularly serious. African unemployment (using the broad definition) increased by 2.9% (from 31.9% to 34.8%) as compared to other racial categories. Male unemployment (3.6%) increased more than females (0.8%), and youth unemployment was significantly increased, by 6.1% in the age-group 15-24 and by 2.3% over 25. Those who completed matric (the school leaving examination) were more affected (3%) than those without (1.9%) suggesting the possibility of cutbacks affecting this group that were in all likelihood paid more highly. This meant that an already bad situation was worsened. In 2008, unemployment for 'Africans' (at 31.9%) was higher by almost 10 percentage points than other groups (Coloured at 21.1%). Female unemployment (32.9%) was slightly higher than their male counterparts (31.9%) and alarmingly, half of the youth were unemployed, at 50.3% in terms of the broad definition and 44.5% in terms of the narrow, with those between 15-24 (49.9%) higher than those above 24 (30.7%). Equity measures that were already under stress were therefore not assisted by the recession.

Table 1. Employment indicators in recession (2008 and 2009)

		2008 (Qtr 2)	2009 (Qtr 2)	Difference	Comment
Unemployment (Overall)	Broad Unemployment (%)	27.1	31.2**	4.1	Increase in absolute numbers of unemployed from 5.12 million in 2008 (Qtr 2) to 5.58 in 2009 (Qtr 2) (increase of 0.46 million). Also an Increase in discouraged workers from 1.1 million (2nd Qtr 2008) to 1,7 million (4th Qtr 2009)***
	Narrow Unemployment (%)	22.7	24.5**	1.8	Job losses: Manufacturing 149300/Retail Trade (223300)/Agriculture, Forestry and fishing (101100)
Unemployment (broad) by Race	African	31.9	34.8	2.9	Young african males with some education hardest hit
	Coloured	21.1	21.2	0.1	
	Indian	13.1	13.8	0.7	
	White	4.9	5.2	0.3	
Unemployment by Gender	Males	22.9	26.5	3.6	
	Females	31.9	32.7	0.8	
Unemployment by Age	Youth Employment (wide)	50.3	57.3**	7	Firms retrenching younger/inexperienced workers and not hiring new job-seekers
	youth unemployment (narrow)	44.5	48.4**	3.9	
	Age (15-24) (overall)	49.9	56	6.1	95% African/increase by > 200 000 (increased by 377 000 (3rd qtr 2009).
	Age (25-34) (overall)	30.7	33	2.3	youth unemployment serious challenge > no impact over 36
Unemployment by educational level	Completed matric	26.9	29.9	3	
	Grades 9-11	35.4	37.3	1.9

Equity Implications

Slow growth due to the recession has perpetuated the skewed racial profile of the South African labour market. Table 2 reflects a snapshot of occupational level by race¹. As the footnote to the table points out, the data is premised on a broad illustrative reflection of the occupational profile of the sector, which is reflective of the key characteristics of the sector by race, rather than definitive statistics.

Clearly this picture complements the view of a racialized labor force. White males still ‘dominate the top echelons of workplaces’; are given recruitment and promotions and benefit the most from training and development opportunities (Nkeli, 2010). It reinforces the view of the Commission for Employment Equity that Whites are, “...continuing to be recruited and promoted in the private sector and are likely to continue to benefit from training and development opportunities” (Nkeli, 2010). Thus despite the range of equity (RSA, 1998b), and skills development legislation (RSA, 1998b), there is still considerable inequality and thus the urgent need for a coordinated response at all levels.

¹ In South Africa, the racial categories defined under apartheid are still used by national government to enable redress and serve as a mechanism for tracking progress towards post-apartheid societal equity. My use of these categorizations attempts to respond to the national imperative.

Table 2. Occupational skills profile of manufacturing employment, by race, 2008-2010 (%)²

	African		Coloured		Indian		White		Total
	2008	2010	2008	2010	2008	2010	2008	2010	
Managers	14	15.6	9.7	7.2	12.5	9.1	63.8	68.2	100
Professionals	25.7	44.8	16.1	9	10.9	10.6	47.3	35.6	100

NATIONAL AND FIRM-LEVEL RESPONSES TO THE CRISIS: SKILLS AND ITS IMPACTS

South Africa's national response to the recession has been particularly counterintuitive to the broad developmental challenges to which it is subject. The first section identifies the key national initiatives that have been employed to respond to the immediate and medium term impacts of the recession, while the second identifies the way in which private sector companies have understood and responded to the most deleterious effects of the recession as it took hold.

National-Level Responses

Government's official response to the recession was contained in a tripartite agreement between government, business, and labour reached on 19th February 2009. Early in December 2008, the then President Motlanthe called a special "Joint Economic Working Group" to discuss the crisis and the response. Social partners agreed to develop a joint response and report back to the President. This report provided the substantial basis for responding to the crisis. The framework agreement reached after intensive negotiation incorporated the following principles:

- Protection of the vulnerable - the working poor and the poor
- Activities should support strengthening the capacity for future growth
- Agreement that bold counter-cyclical action is needed
- Continuing high levels of public investment to counter cycle

² Disaggregating manufacturing by occupation and race creates such small cells that the estimates are liable to be less than accurate to draw a meaningful trend analysis. For example, the 2008 data has only 76 professionals in manufacturing (unweighted), with only 19 African. The 2010 data has 69 observations for professionals of which 27 are African. Anything fewer than 100 observations is problematic, so the conclusions that can be drawn are only illustrative.

- Interventions must be timely, tailored and targeted (Hirsch, 2010)

As a social partnership response agreed to by labor, business and government, there was agreement around the following core principles: financing growth and investment; addressing distressed sectors; avoiding retrenchment and managing it; and addressing the social impact of recession. Significant infrastructural funding was also committed to mitigate the more serious impacts of the crisis. Infrastructural spending is scheduled to reach ZAR787 billion (circa US\$1 billion) over the period from 2009-2011 (part of which was already committed as result of the infrastructural requirements of the FIFA World Cup), and another ZAR390 billion (US\$8.8 billion) in capital spending by state-owned enterprises (Treasury, 2010). In addition, the consequent social spending commitment reflects a degree of seriousness to deal directly with the impacts of the crisis. A budget of ZAR24.8 billion (US\$3 billion) was allocated to health and education and another ZAR4.1 million (US\$0.5 million) for infrastructure. Serious attention was given to the social impacts of the crisis. Importantly, education spending was intended to increase over the next few years, from ZAR127 billion (circa US\$16 billion) in 2008/9 to ZAR169.7 billion (US\$21 billion approx) in 2011/2, an annualized growth of 10% in the period 2008-12 (*ibid*).

The core social protection element of the Government response to the recession was contained in a 'Training Layoff Scheme' (TLS). It was primarily designed to prevent retrenchments (layoffs) resulting from the crisis, by enabling (larger) companies to stave off some employee costs, while still retaining them in anticipation that the worst impacts of the recession could pass. It was, therefore, an attempt to 'delay' the impacts of the recession by reducing the employment costs. A government subsidy designed to enable companies to skill rather than lay-off workers seemed like a valuable strategy to 'manage' retrenchment. By assisting companies to deal responsibly with retrenchments that appeared inevitable, the TLS was designed to prevent large-scale retrenchments in an effort to, "...keep employees working during the economic downturn and re-skill them as an investment for the future economic recovery' (NEDLAC, 2009). Companies and unions would need to agree on the need for this measure in line with company conditions. Finance for this initiative would come from the national skills levy system - the National Skills Fund (ZAR1.2 billion – US\$150 million) and Sector Education and Training Authorities (SETAs) (ZAR500 million – US\$63 million). Only companies that 'were negatively affected by the economic downturn' were supported, with the assumption that if they were not supported, they would be 'forced' to retrench staff. The plan was, therefore, designed to assist staff in the lower echelons of the organization.

Companies were required to prove firstly that their profitability was impacted by the recession, and secondly that if they were not assisted, they would be 'forced' to retrench. While the intent of this program was based on principles designed to reduce the most negative impacts of recession (i.e., joblessness) on larger companies and their employees, it left the rationale for company-level job-shedding intact. It was assumed that retrenching workers was *fait accompli*. It also by default legitimated the view, perhaps an inevitable symptom of business process, that the only way cost-saving could be effected was by shedding personnel at the lower levels of the organization. Even if companies did not see this as a meaningful response, the incentive scheme appeared on the surface to encourage this and provided the rationale for companies to secure funds for this purpose. Thus, while the strategy was well

meaning in its intent to cushion the impact of the recession on those most vulnerable, it reinforced an unintended and unwelcome practice of retrenchment of the most vulnerable.

By its design, therefore, the program did not require proof that job-shedding would be the most effective response to the recession. It was assumed that it was. With respect to other cost-saving and/or profit inducing mechanisms, the reality of seeing lower level vulnerable workers as the most likely cost-saving component appears less than ingenious. The labor union's agreement was secured as they felt the need to reduce the impact of the worst effects of the recession on their membership, which was already being felt by increased retrenchment of their members.

The TLS also perversely (and perhaps tacitly) allowed the entity to leave the staffing of the upper level of the organization intact. This component was most likely to be better paid, arguably better skilled, and the component most in need of transformation. The TLS strategy clearly had potential to hold company recruitment practices accountable in their quest for assistance. It could, therefore, have been better utilized to effect transformation of the workforce of those companies requiring assistance. Instead of the potential to review the nature of structural employment, it left the racially defined employment structure intact and unquestioned. The possibility for company-level transformation offered by the TLS was, therefore, muted. Importantly, in its attempt to respond to the immediate symptoms (i.e., the 'economics' of the crisis) via its 'short-termist' perspective, it not only reinforced assumptions about how to deal with the crisis, but also inadvertently left the racial structure unscathed.

The potential for national development equity and transformational impacts was therefore compromised by the TLS. More saddening was that the implementation of this initiative was considerably less than anticipated. By October 2010, only 6514 workers had been assisted in this initiative. Much of the funds were unspent (ZAR 2.5 billion of ZAR 2.9 billion) (Hirsch, 2010). By October 2010, only ZAR400 million (US\$50 million) was spent. Whether this was a result of bureaucratic processes that needed to be loosened or capacity to unlock funds, it is clear that that a golden opportunity to induce transformation was lost.

Where assistance was provided, government effectively provided support to businesses that were, in many instances, likely to have a skewed workforce profile. The potential to insert a transformative agenda to enable workplace equity in the private sector was therefore lost. The Training Layoff Scheme (TLS) had potential to demand some commitment to equity, as an absolute pre-condition for state assistance. As it was, little attention was paid to the skewed racial structure of the corporations that were likely to be assisted.

Firm-Level Responses

The information derived at company level was gleaned from two exclusive processes. First, a quantitative survey of companies undertaken in 2009 and second, a qualitative survey of 32 key individuals, who were asked to report on skills acquisition practices during recessionary times. They provide important information about the way in which companies understand skills development and recruitment. They were both undertaken prior to the national initiatives being implemented.

Table 3. Company response to impact of recession on key skills development categories: Supply, demand and training spend (%)

	To some/large Extent	Not at all/really	Total
Supply of skilled trade worker or artisan	43	57	100
Demand in the need for skilled artisan/trade workers	60	40	100
Training spent in the organisation	59	41	100

Source: SETA (2010) Employability Survey.

The qualitative survey showed that there was uneven impact on various economic sectors, based on the anticipated buoyancy of the market, and primarily based on perceived government response. For those companies in sectors expecting government intervention and bailout, the recession served as an enabling mechanism for skills growth. While most companies reported that they needed to cut back on skills, some froze training budgets completely. At larger companies, most training was dramatically reduced and enrolment in skills programs virtually halved. In the Automotive Sector, however, artisan training and operator-level training in support of new vehicle model launches and new plant establishment generally continued in anticipation of a renewed government incentive support mechanism. Small- and medium-sized firms reported that they sustained this throughout the crisis. In addition, legislated training such as safety, health and environment was not compromised at every level. The legal requirement for this training form ensures that this continues.

Information from companies also reflected strongly the expectation of companies for effective and assertive state intervention. Most companies surveyed were particularly critical of the government assistance responses referring to them as being too little, too late. Expectations of state intervention in times of recession, while not unusual in conventional contexts, is perhaps heightened and more pronounced in South Africa, where skills levies are used to encourage firm-level skills development.

The quantitative survey provided important data about the nature of skills supply in times of recession and complemented information derived from the qualitative interviews. It showed that the recession has had little positive impact on the nature and quantity of skills supply/availability, as Table 3 indicates.

Importantly, the negative impact on training spend in companies appears to be increasingly dire. Of the companies surveyed, 60% indicated that the recession has had negative impact on training in the organization, with 59% of companies indicating that training spend declined to a significant extent.

Survey data indicated the national trend of a racialized labor force. Whites continue to dominate the top echelons and this view has been reinforced by information undertaken in another survey as depicted in Figure 2 below.

Whites dominate the upper echelons of the organization in the managerial/professional category (73%) and 'Sales and Service (50%) sectors. A little under half (47%) of those employed considered to be in the 'skilled' category were white, suggesting dominant employment/recruitment practice and/or the dearth of black skill in this category.

Figure 2. Demographic profile of labor force by race. Source: SETA (2010) Employability survey.

Clearly, the employment prospects for blacks appear bleak. An overview of recruitment practices in the survey suggests the lack of any transformational impetus. Although business expansion was muted during the crisis, there was evidence that recruitment was still robust during the recession. Most companies reported having to recruit in the skilled components of the organization. More than a third of companies surveyed (36%) recruited at the 'skilled worker' or 'artisan' category, followed by the 'plant and machine operator' (28%) level, and few companies (16%) recruiting at the 'elementary worker' level. Very few firms recruited at the higher echelons such as management (9%) and sales and service personnel (12%), suggesting that the possibility for change in the upper structure is minimized.

Recruitment trends also show a distinct lack of workforce transformation in these times. Table 4 shows the racialized structure of recruitment practices. 'Whites' have been recruited at the upper echelons of the organization (manager, sales and skilled worker levels), and "blacks" at lower levels, 'elementary' and 'plant level operator' level as table 4 shows. Thus, the possibilities for demographic transformation have been muted in recessionary times.

Recruitment during recession is also associated with considerable poaching of experienced personnel from other companies, ensuring that those hired with some experience are able to 'hit the ground running' so as to incur minimal production downtime required for technical and workplace familiarity.

More than two-thirds of companies reported that they recruited from other companies (76%), as opposed to a little over a fifth (24%) recruiting newly trained graduates from colleges and universities. This unsurprising propensity to reduce the 'burden' of training in this time was clearly evident.

The reality of firm-level response was, on the one hand, to cut back on existing training and, on the other, to recruit from an existing pool of skilled workers. The impact on firm-level transformation was, therefore, muted as companies used skills already in the country.

Table 4. Recruitment by occupation and race

	African	Coloured	Indian	White	
Managers/Professionals	33%	5%	7%	55%	100%
Sales/Service/Administration and secretaries	19%	8%	8%	65%	100%
Skilled trade worker or artisan	27%	7%	6%	60%	100%
Plant and machine operators	60%	12%	6%	23%	100%
Elementary workers/Labourers	85%	5%	1%	9%	100%

CONCLUSION

While international attention has been placed on responding to the economy, there are examples of contexts in which skills has loomed large in responding to the current crisis. This is indeed to be welcomed. However, in South Africa, where an economic response targeting sustainability of larger entities has been the focus of the recessionary response, the immediate gains of economic sustainability appeared to have ignored the larger equity imperative bedeviling the country. The crisis provided a golden opportunity to engage workplace equity challenges which are still evident in the private sector. Clearly an examination of the equity and transformation impacts and responses suggests that it has been sacrificed and the national equity project compromised in an effort to reap short term gains. The challenge for transformation of large workplaces in the attempt to achieve a more diverse employee profile of the private sector in South Africa still remains.

The examination of national responses to the crisis, complemented by firm-level data of responses, suggests that the official South African response to the recession impacted marginally on key national development challenges. The ‘Training Layoff Scheme’ introduced by the national government as a response to the crisis to stave off retrenchment provided little consolation to the broader equity challenge. Importantly, it provided the rationale for larger companies to target labor costs of those most vulnerable as a cost-reducing measure, while simultaneously leaving the upper echelons of the organization intact, the area most in need of transformation. The real issue of changing the workforce profile was therefore left for the post-recession era. Importantly, it also left smaller business entities, considered to be a crucial component of the response to the employment challenge, outside of the loop of the assistance plan.

Recruitment practices of companies during this time suggest that transformation imperatives have been significantly undermined. Most importantly, recruitment, where it was occurring, was racially defined, with companies reinforcing their racially defined upper structure by recruiting from an already dwindling pool of white candidates. This is not unsurprising in a context when firms seek what they perceive as the most efficient and effective skills capable of responding to crisis effectively in challenging economic times.

The chapter has argued that the call for state support presented a ‘golden opportunity’ for the establishment of more equitable workplaces. While it is accepted that the possibility for

voluntary equity achievements is much more elusive than anticipated, the call for state support to larger private sector entities provided the opportunity for ensuring equity outcomes. The skills development incentives program could have been a powerful means by which employment equity could have been effectively advanced. The various reports by the equity commission lamenting the lack of transformation in the workplace suggest that all means by the state need to be utilized to achieve equitable workplaces. Perhaps the real challenge is to nudge business to take on the transformation agenda by means that are economically defensible, a regrettable situation, since the transformation imperative has an intrinsically legitimate and plausible business incentive component.

Chapter 22

FOREWORD ADVANCES AND CHALLENGES IN STROKE: HOW ARE MODERN TECHNIQUES CHANGING OUR UNDERSTANDING OF STROKE?

Michelangelo Mancuso*, MD, PhD

Department of Experimental and Clinical Medicine, Neurological Clinic,
University of Pisa, Pisa, Italy

INTRODUCTION

Stroke has a sudden and sometimes devastating impact on both patients and their families. According to the WHO definition, stroke is a cerebrovascular accident caused by “the interruption of the blood supply to the brain (...). This cuts off the supply of oxygen and nutrients, causing damage to the brain tissue.” In reality, a very complex world of numerous biochemical, molecular, and pathological processes is hidden behind this simple definition. Although stroke is most common in older people, it can occur in individuals of any age, including young adults and children. Fortunately, the prospects of preventing and treating stroke are far better nowadays than they were just few decades ago. Today we know a lot more in terms of pathogenesis, risk factors and genetics. Moreover, treatment of stroke has improved dramatically, reducing mortality and the likelihood of long-term disability.

However, many challenges still await physicians and researchers in prevention, understanding of pathogenesis and optimizing treatment of this condition. Stroke remains an emergency for our society; all over the world about 15 million people suffer from cerebrovascular diseases, stroke being the most frequent life-threatening neurological disease and the third cause of death and disability.

With this book we will accompany the readers through the complexity of stroke pathogenesis, from the molecular basis to the most recent advances in term of pathogenesis and treatment. “Advances and challenges in stroke” aims to examine some aspects of interest in the field of cerebrovascular disease, such as the etiology of juvenile and cryptogenic stroke,

* Michelangelo Mancuso: Department of Experimental and Clinical Medicine, Neurological Clinic, University of Pisa, Italy. Email: mancusomichelangelo@gmail.com.

the relationship between heart and brain in the pathogenesis of brain injury, the telemedicine state of the art in reducing door to needle and decision-making times as well as the contribution of modern neuroimaging techniques and of surgical or endovascular treatment in the hyperacute stroke phase.

It has been a great experience to serve as the Guest Editor for this monography. I hope this publication offers a new momentum in advancing the science of stroke. I would like to express my special gratitude to the Nova Publishers for offering us this unique opportunity. I sincerely thank my Director and Assistant Editor of this book, Professor Ubaldo Bonuccelli, for giving me the chance to follow this exciting project, and for having been actively involved in the designing of this challenging book. Moreover, I deeply thank all the authors of this issue for their timely and invaluable contributions to this monography. Finally, I have to thank my young fellows for their daily effort in both managing stroke patients and research activity: Nicola Giannini, Miriam Maccarrone, Vincenzo Montano, Leonardo Ulivi.

Enjoy the reading!

Chapter 23

MONOGENIC DISEASES ASSOCIATED WITH STROKE

***V. Montano, N. Giannini, M. Maccarrone, C. Simoncini, E. Ferrari,
L. Ulivi, G. Siciliano, U. Bonuccelli and M. Mancuso****

ABSTRACT

Ischemic stroke is a complex disorder resulting from the interplay of genetics and environment. In some instances (up to 5% of cases, especially in young adults) stroke is the direct result of a monogenic disease. Among the monogenic causes of stroke, the diseases that most frequently encounter in the adult general neurological practice are CADASIL, Fabry disease and mitochondrial disorders. In many instances, brain magnetic imaging and clinical data may help in the molecular screening. The identification of a genetic cause is important for appropriate counseling and in order to start a correct therapy, where available. Here we review the single-gene causes of ischemic stroke, with special regard to the associated features which can be helpful in the diagnostic process.

Keywords: stroke, genetics, MELAS, CADASIL, Fabry, DNA

INTRODUCTION

Stroke is the most common life-threatening neurological disease, the third largest cause of death and disability in the developed countries and a leading factor in age-related cognitive decline and dementia [1]. Indeed, stroke is considered a multifactorial disorder, resulting from the interaction between many genes and environmental factors. Conventional vascular risk factors like hypertension, diabetes mellitus, obesity, cigarette smoking and atrial fibrillation

* Corresponding author: M. Mancuso, Department of Clinical and Experimental Medicine, Neurological Clinic, University of Pisa, Via Roma 67, 56100 Pisa, Italy. Email: mancusomichelangelo@gmail.com.

account for about 50% of stroke risk; however, these factors do not entirely account for the occurrence of stroke in unexposed populations and also fail to explain the incidence of stroke in select individuals within a population that is uniformly exposed to environmental risk factors [2]. Some of this phenotypic variability has been attributed to genetic differences, with familial patterns of inheritance also providing support.

It is likely that multiple genes are involved in stroke pathogenesis, severity and response to treatment (not dissimilar to other complex polygenic diseases) [3]. Genome wide association studies (GWAS) on a wide range of candidate pathways, such as the haemostatic and inflammatory system, homocysteine metabolism, and the renin-angiotensin-aldosterone system, suggest a weak but significant effect for a large number of single nucleotide polymorphisms (SNPs) [3, 4]. This is a promising approach for the identification of novel biological mechanisms that underlie the development of cerebrovascular disease.

In some instances (up to 5% of stroke cases, especially in young adults) stroke is the direct result of a monogenic disease [5]. The majority of these monogenic disorders begins at young age, and frequently affects multiple organs and tissues. It is important to consider inherited syndromes in the differential diagnosis particularly in cryptogenic stroke and in patients with a family history of stroke. The identification of a genetic cause is important for appropriate counseling and in order to start a correct therapy, where available. Finally, unraveling the mechanisms of disease responsible for monogenic stroke disorders may contribute to future understanding of the pathophysiology of sporadic stroke syndromes.

Here we review the single-gene causes of ischemic stroke, with special regard to the associated features which can be helpful in the diagnostic workup.

SMALL-VESSEL DISEASES (SVD)

Cerebral SVD refers to pathological processes that affect the structure or function of small vessels on the surface and within the brain, predisposing to ischemic and, in some instances, hemorrhagic stroke and diffuse white matter disease [6]. Neuropathology is usually characterized by thickening of the arterial media of cerebral small vessels with encroachment on the arterial lumens (typically due to the deposition of material or hypertrophy of smooth muscle/other connective tissue elements), multiple small deep lacunar infarcts and degenerative abnormalities in the cerebral white matter. Clinically, SVD can progress silently for many years before becoming clinically evident [7].

Currently, there are no specific proven treatments for SVD (with the remarkable exception of Fabry disease), and therapeutic options for secondary prevention are particularly limited compared with those for other common causes of stroke; thus, treatment is entirely symptomatic.

Hereditary forms of cerebral amyloid angiopathy (CAA) are not discussed here because they are much more frequently associated with lobar hemorrhages, microbleeds, cortical petechiae and subcortical hemorrhages rather than ischemic strokes; dementia and diffuse white matter damage are very common in these conditions [8]. Amyloid precursor protein (*APP*) is the gene more frequently involved in most familial forms of CAA [9].

Cerebral Autosomal Dominant (and Recessive) Arteriopathy with Subcortical Infarcts and Leukoencephalopathy

CADASIL is an autosomal dominant (AD) disorder caused by dominant mutations in the *NOTCH3* gene on chromosome 19p13.2-p13.1 [3]. *NOTCH3* encodes a large transmembrane protein receptor located on cell surface expressed in vascular smooth-muscle cells and pericytes, essential for arterial differentiation and development [10]. CADASIL usually presents in youth and adulthood with migraine, transient ischemic attacks (TIA) or strokes, psychiatric disorders and cognitive impairment. It is now recognized as the most common cause of inherited stroke and vascular cognitive impairment in adults [11]. Interestingly, Schmidt H. et al. have shown that 4 single nucleotide polymorphisms (SNPs) in the *NOTCH3* gene are significantly associated with an increased risk and progression of age-related white matter lesions in hypertensives, suggesting that genetic variations in *NOTCH3* also play a role in age-related SVD [12]. Transient ischemic attacks and ischemic stroke in CADASIL occur at a mean age of 47 years (age range 20-70 years), in most cases without conventional vascular risk factors. Ischemic events are subcortical and present in most individuals as lacunar syndromes [13], due to microangiopathy accompanied by the presence of granular osmiophilic material (GOM) of 0.2-1 μm in size in the arterial walls of brain. GOM form deposits in the smooth muscle cells of the media long penetrating arteries supplying subcortical white matter leading to luminal stenosis and reduction in cerebral blood flow [14]. Though changes appear to be most severe in cerebral WM, they may be also observed in the media of dermal, peripheral nerve and muscle arteries; therefore, if molecular genetic testing is not conclusive, the diagnosis could be established by detection of GOM by electron microscopy and immunohistochemistry of a skin or skeletal muscle biopsy [15]. CADASIL should be considered in patients with a history of migraine (which is often the first symptom [13]), especially with atypical prolonged aura, subcortical stepwise dementia manifesting initially with executive dysfunction, recurrent TIA/strokes (before age of 60-yrs), and psychiatric symptoms [3]. Apathy and mood disturbances are typical features. Brain magnetic resonance imaging (MRI) shows white matter hyperintensities typically in the temporal poles, external capsules, periventricular and deep white matter with the highest lesion load in the frontal lobe, lacunar infarcts, dilated perivascular and cerebral microbleeds (located predominantly in the thalamus) [16]. The genetic background may play a role in modulating the overall white matter lesions burden in CADASIL explaining the phenotypic variability between individuals as demonstrated by Gesierich et al. who found a significant association of APO ϵ 2 allele with increased white matter hyperintensities volume [17]. Cardiovascular risk factors may also worsen the phenotype of CADASIL and should be treated aggressively [13]. Given this, prevention of ischemic attacks is commonly based on treatment of vascular risk factors and antiplatelet drugs rather than anticoagulants because of the increased risk of cerebral hemorrhage [11]. However, the benefits of platelet antiaggregates for CADASIL have not been established to date [11].

Cerebral autosomal recessive arteriopathy with subcortical infarcts and leukoencephalopathy (CARASIL) is similar to CADASIL but with earlier onset and systemic symptoms. CARASIL is due to mutations in the *HTRA1* gene localized on 10q26.13, encoding a serine protease belonging to the HTRA protein family that represses signaling mediated by the transforming growth factor- β (TGF β) [18]. The disease is predominant in males, with a male:female ratio of 3:1; to date most patients described in literature (about 50)

have been reported in Japan and China, though it could be an underdiagnosed condition [3]. Clinically frequent initial symptoms are gait disturbance with spasticity and pyramidal signs, and then the clinical pictures evolve with early (between 20 and 50 years) slowly progressive dementia and mood changes [19]. Differently from CADASIL, CARASIL has a multisystem involvement characterized by alopecia, arthropathy, low back pain, spondylosis deformans and disc herniation [20]. Typical neuropathological features are arteriosclerosis associated with intimal thickening and dense collagen fibers, loss of vascular smooth muscle cells, and hyaline degeneration of the media of cerebral small arteries of white matter and basal ganglia resulting in luminal stenosis; unlike CADASIL, GOM within the vascular media is never observed and skin biopsy is not useful for diagnosis [21]. Brain MRI does not allow to differentiate CARASIL from CADASIL with certainty considering that this two SVD share the same pattern of white matter hyperintensity on T2-weighted or fluid-attenuation inversion recovery (FLAIR) images in periventricular and subcortical white matter, anterior temporal lobe, cerebellum, brain stem, external capsule and lacunar infarctions. A typical MRI finding in advanced stage of CARASIL is an arc-shaped hyperintense lesion from the pons to the middle cerebellar peduncles, designated as “the arc sign” by Nozaki et al. [22]. Spinal MRI demonstrates spondylosis deformans and disk degeneration in cervical and lumbar tract [18]. Inhibition of accelerated TGF- β signaling may be in the future an interesting therapeutic approach for CARASIL. Recently, Verdura et al., using a whole exome sequencing approach, found a heterozygous *HTRA1* pathogenic mutation in a family with AD-SVD of unknown etiology and in 10 of 201 additional unrelated and affected probands; they also found a significant difference in the number of likely deleterious variants in cases compared to controls, suggesting a role of *HTRA1* gene in sporadic SVD of unknown aetiology [23].

Fabry Disease

Fabry disease is a rare, X-linked, inherited disorder of glycosphingolipid metabolism [24]. It is a lysosomal storage disorder with progressive multiorgan involvement, caused by a partial or total deficit of α -galactosidase A (α -GalA) enzyme. α -GalA is encoded by *GLA* gene, located on the long arm of chromosome X (Xq22). Clinical manifestations of Fabry disease result from the accumulation of glycosphingolipids, particularly globotriaosylceramid (also called lyso-Gb3) and galactosylceramide in many tissues and cell types, including endothelial cells, kidney, heart and neurons. Tissue damage is thought to be at least partly due to poor perfusion [25].

Progressive involvement of kidney, heart, and cerebral vessels leads to renal failure, hypertrophic cardiomyopathy, and strokes in adults represent major causes of disease-related morbidity [25]. Gastrointestinal symptoms, hypohidrosis, angiokeratomas and corneal opacities (cornea verticillata) are also common and may aid in the diagnostic approach [25]. Neurological presentations of Fabry disease include stroke episodes, painful neuropathy (small fiber neuropathy), and aggressive clinical forms with central multifocal, relapsing, and progressively debilitating symptoms [26, 27]. Atypical neurological presentations (e.g., transient global amnesia [TGA]-like episodes) are rare but possible [28]. Women may remain free of serious complications, but most are symptomatic and can have cardiac disease and stroke. From this point of view, Fabry disease can be considered a dominant X-linked disease

with incomplete penetrance and variable expressivity (higher in males). Variation in clinical manifestations in heterozygous females is attributed to random X-chromosome inactivation.

Fabry disease is a heterogeneous condition, and the diagnosis may require a multidisciplinary approach [29]. Along with progressive renal, cardiac and sensorineural audiological involvement, stroke is a major and often life-threatening burden of the disease; cerebral vasculopathy occurs commonly and leads to ischemic cerebrovascular events at an early age [30]. The posterior circulation seems especially susceptible, and Fabry disease should be considered in the differential diagnosis of all young cryptogenic stroke cases [30]. The most prominent MRI findings are severe progressive white-matter lesions [30]. The “pulvinar sign” (T1-weighted hyperintensity within the pulvinar), when present [26], is also suggestive.

Enzyme replacement therapy (ERT) is now available, making the diagnosis of this disease essential. Early initiation of treatment is needed for improvement in major affected organs with decreased cardiac mass and stabilisation of kidney function, and improvement in neuropathic pain, sweating, gastrointestinal symptoms, hearing loss, and pulmonary symptoms [31]. Treatment of individual symptoms in addition to ERT is needed for many patients, especially those presenting with organ dysfunction.

Other Rare Autosomal Dominant Small-Vessel Diseases

COL4A1 is a gene encoding the type collagen IV $\alpha 1$ chain that causes a spectrum of cerebrovascular phenotypes with overlapping features which comprises autosomal dominant type 1 porencephaly, brain small-vessel disease with hemorrhage, brain small-vessel disease with Axenfeld-Rieger anomaly and hereditary angiopathy with nephropathy, aneurysms, and muscle cramps (HANAC) syndrome [32, 33]. The presence of a *COL4A1* mutation compromises the vascular basement membrane and weakens the vessel, predisposing to rupture. Juvenile stroke is the core clinical features of *COL4A1* small vessels disease, either ischemic (usually lacunar) and hemorrhagic; recurrent intracerebral hemorrhages may occur in non-hypertensive adults who are younger than age 50 years [34]. Other neurological features are infantile hemiparesis, seizures, migraine with visual or sensory aura, intracranial aneurysms, developmental delay, cognitive impairment and dementia. Systemic features include cataracts, retinal hemorrhages, nephropathy with hematuria and bilateral renal cysts and muscle cramps with elevated creatine kinase levels. Brain MRI shows diffuse leukoencephalopathy with deep white matter involvement of posterior periventricular areas, subcortical infarcts, microbleeds and intracranial cerebral aneurysms [34].

Autosomal dominant retinal vasculopathy with cerebral leucodystrophy (RVCL) is a microvascular endotheliopathy presenting with visual loss, stroke and dementia, with onset in the fourth or fifth decade and sometimes a fast clinical course (5 years or less). Cerebral small vessels in RVCL show fibrinoid vascular necrosis, thickened hyalinized vessels with unusual multilaminated basement membranes and with white matter ischemia [35]. RVCL is caused by mutations in *TREX1* (three-prime repair exonuclease 1) gene [36]. The retinopathy is characterized by retinal hemorrhages, macular edema and neovascularization of the optic disc responsive to bevacizumab [37]. Neurological manifestations are TIAs and strokes, progressive cognitive involvement, headache and psychiatric symptoms. In about 50% of

patients, brain MRI demonstrates, in addition to white matter hyperintensities, an enhancing tumor-like lesion with cortical sparing that may resemble a primary CNS malignancy [38].

Homocystinuria

Homocystinuria encompasses a group of mostly autosomal recessive enzyme deficiencies causing very high plasma ($>100 \mu\text{mol/L}$) and urine concentrations of homocysteine [3]. The classic disease is usually caused by deficiency of cystathionine β -synthase (CBS), a pyridoxine (vitamin B6)-dependent enzyme. It should be suspected in patients with multiple organ involvement with infancy or early childhood onset, clinically characterized by developmental delay, cognitive impairment, severe myopia, Marfan-like skeletal abnormalities (i.e., excessive height and long limbs), osteoporosis and thromboembolic events [39]. The measurement of plasma and urine amino acids levels, the assay of CBS enzyme activity, or the molecular genetic testing of *CBS* can establish the diagnosis of classic homocystinuria in a proband. The disease must be distinguished from the milder ($15\text{--}100 \mu\text{mol/L}$) hyperhomocysteinaemia, which is a risk factor for stroke in the general population, generally associated with both deficient food intake of B6, B12 vitamins and folic acid and a common substitution, $677\text{C}\rightarrow\text{T}$, in the gene for methylenetetrahydrofolate reductase (*MTHFR*) [40]. Pathogenesis of stroke in homocystinuria includes early atherosclerosis, carotid intraluminal thrombosis, arterial dissection, small vessels disease and cardiac embolism [41]. Two phenotypic variants are identified, the B6-responsive (usually the milder) and the B6-non-responsive; the vitamin B6-responsiveness is determined by a pyridoxine challenge test; however, it can be predicted by the genotype [42]. Screening for subclinical hyperhomocysteinaemia in young adults with premature stroke is essential even in absence of classic phenotypic features of homocystinuria, as complications can be reduced [41].

STROKE-LIKE EPISODES

Stroke-like episodes (SLE) resemble ischemic stroke, but they do not usually have an arterial distribution, and histopathological studies don't find lesions of the major cerebral blood vessels.

Mitochondrial Diseases

The "MELAS" acronym (Mitochondrial Encephalomyopathy with Lactic Acidosis and Stroke-like episodes) includes patients who experience stroke-like episodes, with an histological (i.e., ragged red and/or COX-negative fibers in skeletal muscle), biochemical and/or molecular evidence of mitochondrial disease. Lactic acidosis is frequently associated. Adjunctive features may be generalized seizures and cognitive impairment. Typical "mitochondrial red flags" are muscle weakness, exercise intolerance, eyelid ptosis, ophthalmoparesis, axonal multifocal neuropathy, sensorineural hearing loss, pigmentary retinopathy, optic neuropathy, diabetes mellitus, hypertrophic cardiomyopathy and Wolff-

Parkinson-White syndrome, migraine, short stature [43]. The commonest mutation associated with MELAS is the m.3243A > G in the mitochondrial DNA (mtDNA) gene encoding the mitochondrial tRNA leucine 1 (MT-TL1) [44]. However, other mtDNA mutations may cause SLE as well; for example, they can be encountered in the clinical spectrum of the m.8344A > G mutation [45]. Gene analysis for mtDNA can be performed in muscle samples and urinary sediment, because these analyses are less sensitive in blood cells [43]. If the m.3243A > G mutation is absent in the skeletal muscle, the entire mtDNA should be sequenced from the muscular DNA. Genetic studies on blood cells are more useful for nuclear DNA. On the other hand, some nuclear gene mutations (i.e., in *POLG* and *PEO1* genes, encoding respectively the mitochondrial polymerase gamma and the helicase “Twinkle”) can cause a MELAS-like syndrome [46, 47].

Among the affected patients, the most severe COX deficiency (associated with the highest proportion of mutated mtDNA) was observed in the leptomeningeal and cortical blood vessels' wall (in the whole brain), supporting the hypothesis of a vascular mitochondrial dysfunction in the pathogenesis [48]. There is consensus about the vasogenic oedema nature of the SLE lesions; unfortunately, evidences in treatment of SLEs come from single-case reports or small case series and no standardized therapy is available to date [49]. L-arginine is usually administered intravenously in a dosage of 0.4-0.5 g/kg, and may be not only effective for the SLE in the acute phase but also for concomitant refractory epilepsy; it should be switched to long-term oral supplementation after the acute phase [49]. SLE may also improve with corticosteroids, as observed in single cases [50]. Other molecules (i.e., creatine, coenzyme Q10, idebenone) have been suggested to be potentially beneficial in single case reports [50]. Until effective drugs will be available, the treatment of choice may be represented by the combination of L-arginine against the vasogenic oedema, with anti-epileptic drugs and supportive care when needed [51]. Drugs with potential mitochondrion-toxic actions (i.e., valproic acid, metformin, etc.) have been recently reviewed elsewhere [51] and should be avoided.

Familial Hemiplegic Migraine

Familial hemiplegic migraine (FHM) is an autosomal dominant classical migraine subtype that typically includes fully reversible weakness of half the body which can last for hours, days or weeks and other symptoms like visual disturbance (the most common), sensory loss or dysphasia [52]. Basilar migraine and cerebellar signs (ranging from nystagmus to progressive, usually late-onset, mild ataxia) are present in 40-50% of cases. Episodes of reversible coma, SLE, seizures, progressive ataxia, psychosis and severe intellectual disability are uncommon [53]. While FHM often have an earlier onset than typical migraine, the frequency of attacks tends to decrease with aging. So far, three genes are known to be associated with FHM: *CACNA1A* (FHM1), *ATP1A2* (FHM2), and *SCN1A* (FHM3). Mutations in the *CACNA1A* gene (encoding the alpha1A sub-unit of the voltage-gated calcium channels in neurons) are responsible for 50% of FHM cases [54]. Genotype-phenotype correlations have been described [54]. MRI does not show white matter abnormalities or sub-cortical strokes, but it may reveal various degrees of vermian cerebellar atrophy [53]. Treatment options include acetazolamide, migraine prophylaxis and antiepileptic drugs [55].

DISORDERS OF THE CONNECTIVE TISSUE

COL4A1-associated disease has been considered above (“Small-vessel diseases”).

Ischemic stroke is a well-known complication of several inheritable connective tissue disorders, which more frequently cause large-vessel diseases. Apart from those considered in the following paragraphs, many other hereditary connective tissue diseases may, rarely, present with stroke [56].

Marfan Syndrome

Marfan syndrome is an autosomal dominant disorder, caused by mutations in the fibrillin 1 (*FBN1*) gene, affecting the musculoskeletal and cardiovascular systems and the eye. The typical clinical features are myopia, displacement of the lens, bone overgrowth (disproportionately long extremities for the size of the trunk), joint laxity, scoliosis, *pectus carinatum* or *excavatum*, arachnodactyly and dilation or dissection of the ascending aorta [57]. Cerebrovascular complications of the disease include TIAs, ischemic strokes, subdural haematomas and cerebral aneurysms [58]. A cardiac source of embolism is the leading cause of ischemic stroke in Marfan syndrome, followed by cervical artery dissection [59].

Vascular Ehlers-Danlos Syndrome

Ehlers-Danlos syndrome type IV, the “vascular” type, is an autosomal dominant disorder, resulting from mutations in the collagen III gene (*COL3A1*), encoding for collagen type III. Vascular Ehlers-Danlos syndrome leads to severe fragility of connective tissues, predisposing arteria, uterus and intestine to ruptures, sometimes during surgical and radiological treatments. Other systemic clinical features include easy bruising, thin skin with observable veins, characteristic facial tracts (thin nose, lips and philtrum, small chin, large eyes), acrogeria, tendon or muscle ruptures and chronic joint subluxations or dislocations. Cerebrovascular events are common and include spontaneous cervical arterial dissection, intracranial aneurysms, subarachnoid hemorrhages, carotido-cavernous fistulae [60].

Pseudoxanthoma Elasticum

Ischaemic stroke can occur in the natural history of Pseudoxanthoma elasticum, an autosomal recessive (rarely dominant) disease due to *ABCC6* (ATP-binding cassette C6) gene mutations. Pseudoxanthoma elasticum is a systemic disorder that affects the elastic tissue of the skin, the eye, the cardiovascular and gastrointestinal systems. Individuals most commonly show skin changes (like increased elasticity, yellow-orange papular lesions), ocular abnormalities (retinal angioid streaks), gastrointestinal bleeding and hypertension. Degenerative changes of vascular wall, with various degrees of intima thickening due to a patchy proliferation of the fibroelastic components, cause arterial narrowing, increasing the

risk of ischemic stroke (large vessels or small vessels disease subtypes) and, sometimes, predisposing to cervical artery dissection [61].

OTHER MONOGENIC DISEASES

Hereditary prothrombotic disorders (e.g., Factor V Leiden mutation; protein C, protein S, antithrombin deficiencies) are more commonly associated with cerebral venous thrombosis and will not be discussed here.

Sickle Cell Disease

Hemoglobin S (HbS) results from a substitution of thymine for adenine in the beta chain gene of the protein. Sickle cell disease is due to a homozygous or a compound heterozygous state, the last with HbS occurring in combination with other hemoglobinopathies. The disorder is most prevalent in African or African American descent. The mutation causes polymerization or aggregation of deoxygenated hemoglobin within red blood cells. Patients commonly suffer from chronic compensated hemolytic anemia, mild jaundice, and intermittent vaso-occlusive crises (excruciating pain in the back, chest, and extremities). Vasculopathy in sickle cell disease has a complex pathophysiology, involving abnormal red blood cell adherence to the endothelium, oxidative stress, endothelial cell dysfunction, hypercoagulable state, chronic inflammation and vasomotor tone alterations, leading to nitric oxide depletion [62]. Stroke in sickle cell disease is mainly due to the large-artery vasculopathy of the proximal middle cerebral arteries and intracranial internal carotid arteries. Other features of central nervous system involvement are TIAs, hemorrhagic strokes (associated with aneurysms), silent ischemic lesions in the territory of penetrating arteries, seizures, spinal cord vascular events and Moyamoya-like syndrome that occur in about 25% of individuals by the age of 45 years [63]. Transcranial Doppler (TCD) ultrasound detects narrowed arterial segments and helps predict which patients are at higher risk of stroke [64, 65]. Transfusion programs with the goal of decreasing the HbS below 30% significantly reduce stroke risk in patients with abnormal TCD [66]. Other treatment options include hydroxyurea and, in some instances, bone marrow transplantation.

Hereditary Hemorrhagic Telangiectasia

Hereditary hemorrhagic telangiectasia (HHT) is an autosomal dominant disease, characterized by the presence of multiple arteriovenous malformations (AVMs) [67]. HHT is caused by the mutation in two genes involved in the TGF- β /BMP signaling, *ENG* (HHT1) and *ACVRL1* (previously named *ALK1*, HHT2), but recently HHT has been also associated to *SMAD4* (typically with concomitant juvenile polyposis) and *GDF2* [68]. Spontaneous and recurrent epistaxis from juvenile age, mucocutaneous telangiectases and gastrointestinal bleeding, usually after the age of 50 years, are the common manifestations of the disease. AVMs are found in many organs, including brain, lung, liver, pancreas and bowel.

Table 1. Adjunctive clinical features in juvenile stroke

	Nervous system	Cardiovascular system	Eye	Skin	Others
Fabry disease	Pain, hearing loss, white-matter lesions	Hypertrophic cardiomyopathy	Corneal opacities	Hypohidrosis, angiokeratomas	Renal failure, gastrointestinal symptoms
CADASIL	Migraine with aura, psychiatric disorders, dementia, leukoencephalopathy				
CARASIL	Leukoencephalopathy, cognitive involvement			Alopecia	Arthropathy, back pain, spondylosis
<i>COL4A1</i>	Infantile hemiparesis, seizures, visual loss, dystonia, hemorrhagic strokes, migraine, dementia, leukoencephalopathy				
<i>TREX1</i>	Cognitive involvement, headache, psychiatric symptoms, leukoencephalopathy		Retinal telangiectasias, microaneurysms and capillary obliteration		
Homocystinuria	Mental retardation		Dislocation of the lenses		Marfan-like abnormalities
MELAS	Generalized seizures, cognitive involvement, hearing loss, axonal multifocal neuropathy, migraine	Hypertrophic cardiomyopathy, Wolff-Parkinson-White syndrome	Eyelid ptosis, ophthalmoparesis, pigmentary retinopathy		Lactic acidosis, muscle weakness, exercise intolerance, diabetes mellitus, short stature
Familial hemiplegic migraine	Atypical long-lasting aura, ataxia				
Marfan syndrome		Aortic and cerebral artery dissection	Ectopia lentis		Pectus carinatum or excavatum, reduced upper-to-lower-segment ratio, scoliosis
Vascular Ehlers-Danlos syndrome	Intracranial aneurysms	Arterial dissection and rupture		Easy bruising, thin skin with visible veins	
Pseudoxanthoma elasticum			Angioid streaks	Increased elasticity, yellow-orange papular lesions	Hypertension
Sickle cell disease	Haemorrhagic strokes, seizures, spinal cord vascular events	Vaso-occlusive crises with pain			Hemolytic anemia, mild jaundice
Hereditary hemorrhagic telangiectasia	Arteriovenous malformations, embolic stroke, abscesses	Multiple arteriovenous malformation of bowel, lung, liver		Mucocutaneous telangiectases	Recurrent epistaxis

Neurologic events are described in up to 40% patients with pulmonary AVMs [69]. The commonest are TIAs or embolic stroke, as a consequence of right-to-left blood shunting associated to a pulmonary AVMs (cerebral paradoxical embolization) [70, 71]. TCD ultrasonography and transesophageal echocardiography, both with saline contrast, are useful in identifying patients with right-to-left shunts and may help, in turn, to suspect pulmonary AVMs [72]. Hemorrhagic stroke is also possible, due to rupture of a brain AVMs; the presence of multiple brain AVMs should raise the clinical suspicion of HHT [73]. Brain abscesses caused by septic emboli bypassing the filter of the pulmonary circulation and spinal AVMs are other findings in about 5% of HHT. Screening for pulmonary AVMs with TCD ultrasonography and preventive treatment should be recommended to patients with HHT [67].

CONCLUSION

Table 1 reports the clinical features commonly associated with stroke in the presented monogenic disorders. A complete clinical evaluation with the support of the brain imaging frequently allow the molecular diagnosis of a suspected monogenic stroke. Accurate diagnosis has therapeutic implications in some of these disorders, including Fabry, mitochondrial and sickle cell diseases.

Among the above mentioned monogenic causes of stroke, CADASIL, Fabry and mitochondrial diseases are the most common in the adult population. The minimum prevalence of CADASIL in general population is thought to be 1 in 25-50.000, with a mutation prevalence estimated at 4.14 in 100.000 and an individual risk of 1 in 13.500 to develop CADASIL in the general population [74]. Fabry disease is pan-ethnic and the reported annual incidence of 1 in 100.000 may underestimate its true prevalence [25]. It may explain approximately 1% of all strokes in the young [75, 76].

A simple and available method to screen for Fabry disease in large populations has been developed using fluorometric or tandem mass spectrometry of α -GalA activity in dried blood spots on filter paper [77, 78]. For mitochondrial disorders, the scenario is much more complex; about 10 in 100.000 people have clinically manifest mtDNA disease, making this one of the commonest inherited neuromuscular disorders; the m.3243A > G mutation has a minimum point prevalence of 1 in 6.135, being the most common pathogenic mtDNA mutation [79, 80]. The reported epidemiological data are likely to be underestimates, due to missed diagnoses of these rare disorders, so further studies are strongly needed in order to better define the impact of monogenic strokes in general population.

Chapter 24

FABRY DISEASE: AN INTRODUCTION FOR NEUROLOGISTS

Atul B. Mehta*

Professor of Haematology, Royal Free Hospital,
University College London School of Medicine, London, UK

ABSTRACT

Fabry disease (OMIM 301500) is an X linked lysosomal storage disorder due to deficiency of alpha galactosidase A (AGAL–A). Diverse mutations in the AGAL–A gene cause a multi-system disorder, often presenting in childhood but complicated by organ damage (principally renal failure, cardiomyopathy and cerebrovascular disease) and limitation of life expectancy in adulthood. Missense mutations in the gene are associated with residual enzyme activity and an attenuated form of the condition which typically presents in adulthood.

Neurological manifestations include small fibre neuropathy, abdominal pain, disturbances of eye and ear function, reduced sweating, depression, cognitive impairment and stroke or transient ischaemic attack.

Management of patients and families with Fabry disease requires a multidisciplinary team administering specific and supportive therapies. Treatment with enzyme replacement therapy has improved the outlook for patients and families with Fabry disease but there remains a need for improved specific treatment approaches.

INTRODUCTION

Fabry disease (OMIM 301500) is an X linked lysosomal storage disorder due to deficiency of alpha galactosidase A (AGAL–A) [1]. The condition was described simultaneously and independently by Johannes Fabry [10] and William Anderson [11], who both observed the characteristic skin rash as an important feature of the disease. Null mutations in the AGAL–A gene result in absent enzyme activity in males and boys typically

* Corresponding Author's Email: atul.mehta1@nhs.net.

present with features of classical Fabry disease. However, milder oligosymptomatic forms, presenting in adulthood and often affecting a single organ system, are increasingly recognised. These attenuated forms are associated with missense mutations and residual enzyme activity; adult males and females typically present to a range of adult physicians (e.g., nephrologists, neurologists and cardiologists) with signs of organ damage. The diagnosis is often delayed [40]. Neurological complications in childhood include acroparasthesia, hearing loss, tinnitus, cornea verticillata and abdominal pain [15]. Adults can present with stroke or transient ischemic attack at a young age (less than 55 years [27]). Fabry disease is also associated with a high prevalence of depression and older patients may develop cognitive impairment [38]. Two preparations of enzyme replacement therapy (ERT), agalsidase alpha (Replagal R, Shire HGT and agalsidase beta, Fabrazyme R, Genzyme/Sanofi) are licensed in Europe, Canada, Asia and South America while only agalsidase beta is approved by the FDA in the US [43]. Adjunctive care coordinated through designated expert centres and delivered by local physicians is recommended.

EPIDEMIOLOGY

Fabry disease (alpha galactosidase A, GLA, deficiency) in its classic form is generally considered the second most prevalent lysosomal storage disorder, after Gaucher disease [1, 2] with an estimated incidence ranging between 1:40,000 to 1:170,000 persons. All ethnic groups are affected. However newborn screening has revealed a higher incidence (about 1 in 3100 male births, [3]) of mutations in AGAL-A that are likely to be neutral but may result in a later onset and less severe phenotype. The incidence of Fabry disease among nearly 35 000 neonates screened in Austria is 1:3859 [4]. It may be estimated that the incidence of Fabry disease requiring treatment in Europe and North America is of the order 1 in 30-40,000.

ETIOLOGY AND PATHOGENESIS

Fabry disease is caused by the partial or complete deficiency of a lysosomal enzyme, α -galactosidase A. As a result of this enzyme deficiency, neutral sphingolipids with terminal α -galactosyl residues [predominantly globotriaosylceramide (Gb3)] accumulate in the lysosomes of different tissues and fluids (epithelial cells of glomeruli and tubules of the kidneys; cardiac myocytes; ganglion cells of the autonomic system; cornea; endothelial, perithelial, and smooth muscle cells of blood vessels; and histiocytic and reticular cells of connective tissue). Elevated levels of globotriaosylsphingosine (lyso-Gb3), which is the deacylated derivative of Gb3, have been found to correlate with disease severity in males and females [5]; and urinary levels of Gb3 have also been considered to be bio markers of the condition [6]. Lyso Gb3 has also been shown to stimulate the proliferation of vascular smooth muscle cells; and to be a mediator in signalling processes pathological significance in pain channels [7] and in kidney podocytes [8]. Lyso Gb3 has been shown to inhibit the activity of AGAL-A [5] and it has been suggested that elevated levels in females could be of pathogenic significance. Although the condition is X linked, heterozygous females are frequently affected and may be as severely affected as hemizygous males. Clinical symptoms typically

occur a decade or so later in females than in males and organ damage is usually less severe. The Lyon hypothesis is that one X chromosome is inactivated on a random basis in female tissues, while the other provides the genetic information. Skewed X chromosome inactivation, whereby the mutant X chromosome is expressed more frequently than the wild type, has been proposed recently as a major prognostic factor in heterozygous females [9].

The gene GAL for α -galactosidase A is located at the Xq22.1 region. More than 600 mutations have been identified in the AGAL-A gene [1], including missense, nonsense mutations and single amino acid deletions and insertions. Classic Fabry disease is typically associated with null mutations and absent enzyme activity in males. Non-classic Fabry disease is associated with mutations which encode enzyme of reduced activity or stability. Most of these mutations are 'private,' having been identified only in individual families. Some (e.g., the p.N215S mutation, which seems to have a high prevalence in the UK) have been associated with single organ (e.g., heart or kidney) or late onset variants and patients have normal levels of urinary Gb3, despite having clinical evidence of Fabry disease.

CLINICAL MANIFESTATIONS (TABLE 1)

Classic Fabry disease presents in boys from age 2-3 years with symptoms of a peripheral neuropathy - pain in the hands and feet (acroparasthesia) or cramping abdominal pain with diarrhea or constipation.

Late onset/single organ Fabry disease is much commoner. It presents in adulthood, the skin is rarely involved, there is predominant involvement of a single organ (kidney, heart or CNS) only, and the condition progresses more slowly than classic Fabry disease. Both forms of the condition can affect females; and X chromosome inactivation studies may help to predict the prognosis in females.

Skin and General Manifestations

These were highlighted in the original descriptions of the disease [10, 11].

Angiokeratoma (AK), are the cutaneous hallmark of Fabry disease [12] present in 70% of males and 39% of females. They may be widespread or grouped. In males lesions are typically within the 'bathing trunk' area (genitals, buttocks, lower abdomen, umbilicus, groins, inner thighs and sacrum). AK are also seen on the proximal limbs, particularly their medial aspects, the elbows and knees, the palms and soles, and over the distal phalanges of the digits and on the lips. In females AK are usually sparsely distributed and may occasionally occur in a dermatomal distribution. The commonest sites are the trunk and proximal limbs. Female genital lesions are relatively infrequent.

In both sexes, the presence of cutaneous vascular lesions (CVL), namely telangiectases and/or angiokeratoma has been associated with higher disease severity scores and a higher prevalence of major organ involvement [13]. These findings demonstrate the importance of dermatological assessment and its possible predictive value in terms of systemic morbidity.

Facial features: A "pseudo-acromegalic" facial appearance has been described in some families with Fabry disease and this appears to be commoner in patients with widespread angiokeratomas and classical disease at the more severe end of the spectrum [14].

Table 1. Clinical Manifestations

• Skin – Angiokeratoma – Telangiectasia – Raynaud’s phenomenon – Lymphodema – Hypohidrosis – Hyperhidrosis • Renal – Chronic renal failure • Cardiovascular – Hypertension – Coronary vascular disease – Left ventricle hypertrophy – Valve disease – Arrhythmias – Elevated high-density lipoprotein • Neurologic/psychiatric – Acroparesthesias – Cerebrovascular disease – Dementia – Depression – Increased suicide ideation • Ocular – Cornea verticillata – Conjunctival vessel aneurysms – Increased tortuosity of retinal vessels – Fabry cataract • Gastrointestinal – Diarrhea – Nausea – Vomiting – Postprandial flank pain – Malabsorption • Others – Hearing loss and tinnitus – Hypothyroidism – Obstructive airway disease – Osteopenia and osteoporosis – Anemia
--

Lower limb oedema and lymphedema, particularly affecting the limbs, is frequently observed in Fabry patients. Lymphoedema was cited in the original description of FD [11] and Registry data from the Fabry Outcome Survey (FOS) on more than 700 patients confirms that reversible peripheral oedema of the lower limbs was present in 25% of Fabry males and

17% of females; lymphoedema was present in 16% of males and 7% of females. The mean age of onset was 37 years for males (range 13-70) and a decade or so later for females [12].

Abnormalities of sweating and temperature sensation: Reduced sweating is a classical feature of Fabry disease and thought largely to be a consequence of autonomic neuropathy, though substrate accumulation within sweat glands may play a role. Hypohidrosis was reported by 53% of males and 28% of females, with earlier onset in males (23 vs 26 years). Anhidrosis was described by 25% of males, but only 4% females [15]. Heat intolerance is a commonly associated and disabling symptom, resulting in reduced exercise tolerance, nausea, dyspnoea, light-headedness and headache, or complete collapse with loss of consciousness. Hyperhidrosis may also occur, more commonly in females than males: 11.9% of 369 females versus 6.4% of 345 males [16]. This is higher than the estimated prevalence of 1-2.8% of the general population in the US [34]. In a majority of Fabry patients it affects palms and soles and is not generalized. "Cold intolerance" and the development of pain in the extremities in cold environments is a frequent complaint amongst Fabry patients. More recently, Raynaud's phenomenon, has been documented in 8% of 710 females and 11% of 644 males [15]. This reversal of the sex ratio and high prevalence in males suggest a possible causal link to the underlying Fabry disease. This abnormal vasoreactivity of digital vessels could be related to autonomic dysfunction. Abnormalities of nitric oxide synthetase and increased oxidative stress in vascular endothelium and smooth muscle might also be important triggers [17] for Raynaud's and these observations may be relevant to the cerebrovascular circulation (see below).

Systemic Disease Manifestations

Fabry disease is a progressive, multi-system disorder which typically results in a global reduction in quality of life of affected individuals. Symptoms in childhood [18] typically relate to lethargy, tiredness, pain, cutaneous abnormalities, changes to sensory organs and often gastrointestinal disturbances. In early adulthood patients may suffer extension of any of the above symptoms and often develop lymphodema, proteinuria and the first signs of renal, cardiac or central nervous system/cerebrovascular disease. In late adulthood (age >30 years) symptoms include worsening of the above and more severe organ dysfunction (cardiac disease, renal disease and cerebrovascular disease).

Neurologic Findings

Acroparasthesiaes occur in 80-90% of affected individuals and typically occur in the first decade. Patients describe the sensation as pain, feeling like pins and needles in hands and feet often radiating proximally. Triggers include increased body temperature, exercise or stress. Pain typically declines over time and this may be due to damage to nerve fibres as a result of inflammation and substrate accumulation.

Sensory Organ Abnormalities

The commonest ocular finding is cornea verticillata (opacities in the cornea characterised by one or more lines radiating from the near the centre of the cornea) which occurs in over 90% of males and 70% of females. Other changes include increased tortuosity of retinal vessels, optic atrophy, cataracts and lenticular changes. The extent of ocular abnormalities correlates with the overall extent of the disease [19]. A recent study has also demonstrated genotype-phenotype correlations within the ocular manifestations, such that individuals with

nonsense mutations have more severe manifestations than those with missense mutations [20]. Tinnitus and high frequency sensory neural hearing loss are also common manifestations occurring in over 50% of subjects. Sudden deafness and dizziness due to vestibular pathology can also occur.

Gastrointestinal Changes

Cramping abdominal pain, nausea, diarrhoea and occasionally constipation are frequent and are often the presenting symptom [21]. The pathogenesis is probably related to neurologic abnormalities.

Organ Damage

Renal manifestations are seen in over 90% of males [22]. Micro-albuminuria and hyperfiltration are early features, proteinuria is typically seen in the third and fourth decades and progressive decline in renal filtering capacity occurs. Females frequently show proteinuria although progression to end stage renal failure is less common. A renal variant of Fabry disease has been described in patients with decreased, but not absent alpha-galactosidase A activity; these patients lack other characteristic manifestations [1].

Cardiac manifestations are a constant feature and increasingly recognised as the major cause of death in both male and female patients [23, 24]. Substrate deposition can be demonstrated throughout the myocardium, valves and conduction system and is often accompanied by an inflammatory cell infiltrate. A common presentation is with left ventricular hypertrophy but mitral valve prolapse, arrhythmia and coronary artery disease can all be present. A cardiac variant [1] has been described in patients with reduced but not absent alpha-galactosidase A activity and presents later in life (often above 40 years) with predominant cardiac symptomatology.

Stroke

Cerebrovascular manifestations include ischaemic or haemorrhagic strokes occurring early in life, transient ischaemic attack and strokes affecting the posterior circulation. Stroke is often reported as the presenting feature of Fabry disease and Fabry disease should be considered in the differential diagnosis of young patients with cryptogenic stroke. One European study [25] has suggested that up to 5% of males and 2.5% of females aged under 55 years with cryptogenic stroke may have Fabry disease; however, this has not been confirmed.

Stroke is frequently a devastating complication of Fabry disease and the cost effectiveness of ERT would be substantially improved if a clear impact of ERT on frequency and severity of stroke were demonstrable. The incidence of stroke in Fabry disease is much higher than in the general population, both in males and females, and strokes tend to occur at a younger age. Amongst diagnosed Fabry patients, the incidence of stroke and TIA is 7-11% of males and 4-6% of females respectively [26, 27]. Stroke is often the first manifestation of Fabry disease [7]. Typically, stroke occurs in advanced Fabry disease among patients who also have cardiac and renal disease, may be hypertensive, and frequently have other risk factors for thrombosis (e.g., Factor V Leiden [28]). Both haemorrhage and thrombosis can occur and there seems to be an increased incidence of strokes in the posterior circulation. The mechanism of stroke in Fabry disease is likely multifactorial and incompletely understood. Occlusive vasculopathy is certainly an important contributor to the pathogenesis of stroke in Fabry, as in all situations. Advanced atheroma has been demonstrated in a Fabry patient who

died of cardiovascular disease despite prolonged ERT [29]. The vascular tree is often markedly abnormal in Fabry disease and dolichoectasia is often observed. The posterior circulation is more often involved in Fabry patients than among stroke patients generally. The diameter of the basilar artery has been proposed as a marker of the degree of vascular abnormality in Fabry patients. Inflammation may play an important contributory role. Alterations in adhesion molecule expression leading to disturbed metabolism of nitric oxide synthase (NOS), oxidative stress [30] and increased peripheral blood myeloperoxidase have been reported [31].

The data on cerebral blood flow in Fabry disease are contradictory. Autoregulation of blood flow is known to be disturbed in Fabry disease. Global regional cerebral glucose utilization (rCMRGlu) is decreased and it would be expected that this would promote increased cerebral blood flow. Hilz et al. [32] used transcranial Doppler sonography to assess cerebral blood flow velocity (CBFV) and cerebral autoregulation in 22 Fabry patients (24 controls). Both parameters were reduced in Fabry patients compared to controls. In contrast, Moore et al. [33] used similar techniques and concluded that CBFV was actually increased in 26 subjects with Fabry disease and that ERT with agalsidase alfa reduced it toward normal levels. Uceyler et al. [34] prospectively studied 68 patients with Fabry disease by extracranial and transcranial Doppler sonography and concluded flow measurements were normal in Fabry patients and ERT had no impact on them. MRI scans in Fabry patients often show increased numbers of non-specific 'white matter lesions (WML) which are an indicator of vasculopathic damage. Fellgiebel et al. [35] examined serial MRI scans among Fabry patients being treated within the Fabrazyme phase IV study and reported that the WML burden was more likely to remain stable among the 25 ERT – treated patients than among 16 patients in the placebo group. Theoretically, one may imagine that if ERT has a positive effect on renal and cardiac disease, it may at least delay if not reduce the risk of stroke. However no convincing data have been produced to indicate an impact of ERT on stroke in Fabry disease. Adjuncts to ERT including good control of blood pressure, anti – arrhythmic therapy, aspirin or anticoagulants as appropriate are very important. By improving the plasma lipid profile, statins may be expected to reduce the risk of stroke in Fabry patients. Statins also have a range of beneficial effects on the different isoforms of NOS, as well as anti -inflammatory and anti-thrombotic effects; and they have been recommended for Fabry patients [36].

Other Manifestations

Global manifestations of Fabry disease include lethargy, tiredness, failure to thrive in children and anaemia. Depression is frequent and often under diagnosed, affecting up to 50% of Fabry males and females [37]. Sexual activity is often affected by the presence of angiokeratomas in the genital region and can lead to decreased self esteem and libido. Autonomic dysfunction is under recognised and can lead to hyperhidrosis, abnormal tear and saliva formation, abnormal cardiac reactivity, gastrointestinal dysmobility, altered pain and temperature perception and peripheral oedema. Endocrine abnormalities are uncommon but osteopenia and hypothyroidism are well described. Pulmonary abnormalities are under recognised; Fabry disease can lead to an obstructive airways pattern in some patients but asthma is the presenting feature in other patients. In contrast to other lysosomal storage disorders cognitive impairment is not generally seen, however, older patients (above 50 years) are increasingly seen with memory loss, global intellectual deterioration, and personality change [38].

DIAGNOSIS/DIFFERENTIAL DIAGNOSIS

The definitive diagnosis of Fabry disease is usually delayed, with a mean time between the onset of symptoms and diagnosis of 15 years. The diagnosis must be confirmed by the demonstration of deficient α -galactosidase A activity in plasma, serum, or leukocytes and the identification of the pathogenic mutation. Female patients have variable, and, occasionally, even normal levels of enzyme activity and DNA confirmation of the diagnosis is essential. Identification of a DNA change is necessary, but not sufficient as genetic variants of unidentified significance (GVUS) are frequently detected. Expression studies of the mutant can be helpful in demonstrating pathological significance [39].

Biopsy of tissues, such as skin and kidney, demonstrates the presence of lipid deposition and multilamellated myelin bodies in electron micrographs (see Figure). As Gb3 deposition starts in utero, prenatal diagnosis can be performed from chorionic villi or culture of amniotic cells, where low α -galactosidase A activity can be demonstrated [1].

The pain associated with acroparaesthesia is often misdiagnosed as rheumatoid arthritis, rheumatic fever, erythromelalgia, Raynaud disease, or simply as “growing pains” [40]. Such delay may allow development of irreversible organ damage.

Figure 1. Skin appearances in Fabry disease with extensive angiokeratoma.

PROGNOSIS AND CLINICAL COURSE

Earlier studies suggested that males with Fabry disease typically die in the 4th or 5th decade, and females live perhaps 15 years longer. More recently, the life expectancy for males has been estimated as 58.2 years (compared to 74.7 in the general US population) and 75.4 years for females (compared to 80 years) [41]. There is also evidence that, whereas renal failure was previously the commonest cause of death, cardiac disease and cerebrovascular disease are increasingly common [23]. Some of these changes may be due to the impact of ERT.

TREATMENT (TABLE 2)

Fabry disease is a multi-system disorder and patients should be assessed within a multi-disciplinary setting. The advent of ERT has meant that patients and families are increasingly assessed in a specialist centre, where they will have access to a physician or paediatrician, dermatologist, and possibly cardiologist/nephrologist/neurologist [42]. Access to audiologists, ophthalmologists, gastroenterologists and psychiatrists/counselors, as well as to genetic counselors and nurses is desirable and available at larger centres. General aspects of supportive therapy may be as important as specific therapy.

Table 2. Treatment of Fabry Disease

SYMPTOMATIC
<i>Angiokeratomas</i> Liquid nitrogen, Electrocoagulation, surgical excision, Laser (pulsed-dye 585-nm, neodymium YAG 1064 nm, combined pulsed-dye and Nd:YAG) and IPL
<i>Lymphedema</i> Manual lymphatic drainage massage and compression
<i>Hyperhidrosis</i> Aluminium chloride hexahydrate, electrophoresis, Botulinum toxin, glycopyrrolate sodium
<i>Raynaud's phenomenon</i> Avoid smoking, cold and vasoconstrictor therapies, Losartan, diltiazem, fluoxetine, sildenafil
<i>Pain</i> Avoid triggers, Diphenylhydantoin, Carbamazepine, Gabapentin
<i>Stroke</i> Anti-platelet, Anticoagulant
<i>Hearing</i> Hearing aid devices, Avoid noise trauma

Table 2. (Continued)

<i>Lungs</i> Avoid smoking, Bronchodilators
<i>Gastrointestinal</i> Pancrelipase, Metoclopramide
<i>Cardiovascular</i> Antihypertensive drugs, Antiarrhythmia drugs, Artificial pacemakers, Implantable defibrillators, Coronary bypass
<i>Chronic renal failure</i> Angiotensin converting enzyme inhibitors Hemodialysis, Allograft transplant
SPECIFIC Enzyme replacement α -Galactosidase B (Fabrazyme), α -Galactosidase A (Replagal)

Zebra bodies

Figure 2. Electron micrograph in Fabry disease showing characteristic ‘zebra’ bodies.

Therapies Directed at Other Organ Systems [42, 43]

Pain is the most disturbing and early symptom, and can sometimes be partially managed with diphenylhydantoin, carbamazepine, or gabapentin. Patients should be encouraged to identify and try to avoid their personal precipitating factors.

For the primary or secondary prevention of stroke and other vascular pathologies, such as retinal artery occlusion, anti-platelet and anticoagulant therapy might be needed.

Metoclopramide and pancrelipase are used to reduce gastrointestinal symptoms. Hypertension must be controlled, as it significantly affects three of the most affected organs, the kidney, brain, and heart. Angiotensin receptor blockade should be undertaken at the first sign of proteinuria and is an important adjunct to ERT in slowing the decline in renal function. Fabry patients are good candidates for kidney transplant in the event of ESRF and the role of ERT in this situation is to preserve the function of other organs. Ancillary care from a cardiac perspective includes consideration of antiarrhythmics, artificial pacemakers, and surgery including septal ablation or even cardiac transplant.

Specific Therapeutics: Enzyme Replacement Therapy

This has been recently reviewed [43]. Two formulations of enzyme replacement therapy have been developed, agalsidase beta (Genzyme, Massachusetts US) and agalsidase alpha (Replagal, Shire HGT). Only agalsidase beta is licensed in the US whereas both formulations are available in most other parts of the world. Agalsidase beta is administered at a dose of 1.0 mg/kg biweekly and is manufactured using a recombinant technology in a Chinese hamster ovary (CHO) cell line. Agalsidase alpha is given at a dose of 0.2 mg/kg biweekly and is manufactured using a gene activation methodology in a human fibroblast cell line. The efficacy of both ERT formulations has been demonstrated in randomized controlled trials [44, 45] and both improve biochemical (e.g., levels of Gb3 in plasma, urine and tissue biopsy) and clinical parameters. The main clinical parameters chosen for study are renal function, pain, cardiac size and function and quality of life. Longer term trials have been reported for both preparations. Long term effectiveness has been demonstrated in Registry studies of agalsidase alpha [46] and agalsidase beta [47]. Both preparations are considered safe and well tolerated. The main side effects are infusion related (fever, temperature) and both preparations can induce antibody formation. Although an impact of antibodies on clinical effectiveness has not been conclusively demonstrated, a recent study suggests they may be important [48]. A large multi-centre study from Canada suggests the two ERT formulations are of equivalent effectiveness [49]. The optimum time for commencement of treatment has not been established but a recent consensus statement [50] has emphasized the importance of early intervention before the onset of irreversible organ damage, in both males and females. ERT is recommended for all symptomatic males and at the first sign of organ dysfunction in females. Patients receiving ERT should be regularly monitored with serial measurements of pain, quality of life, renal and cardiac function. ERT has been shown to improve various aspects of neurologic function including pain, hearing [51], peripheral nerve and sweat function [52] and GI symptoms [53]. The only direct beneficial effects of ERT on CNS abnormalities to have been demonstrated are improvements in blood flow disturbance [33] and reduction in WML burden [35]. Infused enzyme cannot cross the blood brain barrier.

Figure 3. (a) MRI scan to show white matter lesions on FLAIR sequences. (b) There is marked asymmetry of the vertebral arteries and the distal left intracranial segment has a reduced lumen with reduced flow (see arrows); this is due to structural tortuosity of the artery, which is a frequent finding in Fabry disease.

New Treatments

Chaperone-based enzyme enhancement therapy consists of small molecules that rescue misfolded/mistrafficked enzymes from the lysosomes and transport them to the endoplasmic reticulum. Chaperone-based therapy can be administered orally but is useful only for patients with residual enzyme activity [54]. Substrate deprivation (inhibition of an early step in the synthesis of glycosphingolipids) and the infusion of galactose are other therapeutic options that are still in the research state. Gene therapy and hematopoietic cell transplantation are being actively developed [55].

Chapter 25

PATHOGENESIS OF HEMORRHAGIC STROKE

A. Bersano^{*}, MD, PhD

Cerebrovascular Diseases Unit,
C. Besta Neurological Institute, Milan, Italy

ABSTRACT

Intracerebral hemorrhage is the least treatable and often fatal form of stroke. Conventionally, ICH is classified as ‘traumatic’ or ‘spontaneous.’ The spontaneous group, which represents the 80% of cases, is further subdivided into ‘primary,’ when an underlying cause is not identified, or ‘secondary.’ Spontaneous ICH occurs more frequently in males, elderly and Africans or Asians and hypertensive subject. The most important causes of spontaneous ICH are deep perforating vasculopathy, which occurs in nearly 50% of cases, and cerebral amyloid angiopathy, detected in 5-20% of ICH patients. However, given the complexity of the pathophysiology of ICH, including inflammatory pathways, apoptosis, mitochondrial dysfunction acting according to the disease stages, a clear pathogenic mechanism has not still defined. Since ICH is now recognized to be a manifestation of the small vessel disease, it is believed that ICH derived from the interaction between the common cerebrovascular risk factors as well as environmental and genetic factors and vulnerable and fragile vessels.

Keywords: cerebral hemorrhage, risk factors, pathogenesis, genetics, neuroimaging markers, causes, deep vasculopathy, small vessel disease, cerebral amyloid angiopathy, neoplasm, intracranial vascular malformation, cavernous malformation, Moyamoya

INTRODUCTION

Intracerebral hemorrhage (ICH) is defined as a focal collection of blood within the brain parenchyma. It is the second most common form of stroke, accounting for 10-30% of first-ever strokes. A recent meta-analysis including 8145 patients estimated an overall incidence of

^{*} Correspondence to Anna Bersano; Cerebrovascular Diseases Unit, C. Besta Neurological Institute, Via Celoria 11, 20133 Milan (Italy), Tel: +39 02 23942190, email: anna.bersano@istituto-besta.it.

ICH of 24.6 per 100,000 person-years (95% CI 19.7–30.7) and the incidence did not decrease over time [1]. Hospital admission for ICH increased by 18% in the last 10 years, probably due to the increased number of elderly and increasing use of anticoagulants, antiplatelets and thrombolytics [2-3]. ICH is one of the most devastating stroke forms leading to be a major cause of morbidity and mortality worldwide [4]. In fact, despite a significant improvement in the management of ischemic stroke, ICH remains associated with a very high case fatality rate (from 13% to 61%) in the first month and only 38% of patients have been estimated to survive over the first year.

Conventionally, ICH is classified as ‘traumatic’ or ‘spontaneous.’ The spontaneous group, which represents the 80% of cases, is further subdivided into ‘primary,’ when an underlying cause is not identified, or ‘secondary’ (due to identified causes including bleeds into tumors, cavernomas, arterio-venous malformations, CNS infection, cerebral venous sinus thrombosis, bleeding disorders, etc.) [5].

ICH may be classified also as deep (45%), lobar (30-40%) and infratentorial (15%). The site of hemorrhage and its extension to other compartments such as subarachnoid, subdural or intraventricular may be useful for identifying the cause.

RISK FACTORS

Spontaneous ICH occurs more frequently in males, elderly and Africans or Asians [3-8]. Hypertension is the major risk factor for spontaneous intracranial hemorrhage (about 65% of cases) and the risk is higher in young subjects and raises with increasing blood pressure values. In these cases ICH is typically observed in deep brain structures [6-7]. Up to half of patients with hypertension suffering from ICH are unaware of their hypertension and/or they do not assume adequate therapy. Alcohol intake is another risk factor for ICH acting in dose-dependent manner, with higher risk among those subjects with a high daily alcohol intake.

Diabetes mellitus and current smoking are considered weak risk factors [6]. Data regarding lipid levels are controversial since serum triglyceride levels (≤ 0.4 mmol/L) have been associated with an increased risk of ICH [9].

Interestingly, ICH related to oral anticoagulants as well to sympathomimetic drug abuse [10] is increasing. In subjects under warfarin the ICH risk-per-year is 0.3%-1% per patient-year, while a noteworthy increase of ICH risk is detected when the international normalized ratio is > 3.5 [11].

NEUROIMAGING MARKERS

It is now generally accepted that the so-called ‘primary ICH’ represents a feature of small vessel disease [12-13]. Neuroimaging, and particularly MRI, is important not only for distinguishing hemorrhage from ischemic stroke in the acute phase but also to identify some important markers of small vessel disease (SVD) such as leukoaraiosis and microbleeds [13].

In fact, despite major hemorrhage and in some way lacunar strokes can be quite easily observed by conventional CT scan appearing like low density lesions, MRI plays a crucial role in detection of microbleeds and leukoaraiosis [14-15]. White matter lesions (WMLs) are

best seen on T2 weighted MRI scans (including FLAIR sequences) as more or less confluent hyperintense areas bilaterally sited in the hemispheric white matter. T2-weighted and FLAIR MRI have been widely used to quantify also WML load [15]. WMLs are typical both of hypertensive arteriopathy and CAA, with similar lesion distribution [16-17].

Lacunar infarcts, which are frequently associated with WMLs, are identified as small, frequently round or ovoid shapes, CSF density filled cavities with a diameter of 3 to 10-15 mm [18]. Upper limit of 1.5-2 cm differentiate them from striatocapsular and embolic subcortical strokes [14], whereas lower limit of 0.3-0.5 cm is used to differentiate them from smaller perivascular spaces. However, enlarged perivascular spaces (EPVS) were found to be associated with WMLs and lacunar stroke suggesting they could be another feature of SVD [19]. EPVS can be seen acutely on diffusion weighted imaging or as hypointense foci surrounded by an hyperintense rim on MRI T1-weighted and FLAIR sequences typically located in the areas supplied by the lenticulostriate or pontine paramedian arterioles, such as basal ganglia, internal capsule, thalamus and pons but also diffusing in hemispheric white matter [20-21].

MRI technique such as T2*-weighted gradient recalled echo (GRE), sensitive in detection iron deposition, can detect small foci of old hemosiderin deposits, called cerebral microbleeds (CMBs), appearing as black or hypointense lesions. CMBs correspond to focal accumulation of hemosiderin containing macrophages in the perivascular spaces surrounded by inflammatory reaction with activated microglial cells, complement activation, apoptosis and sometimes gliosis [22]. CMBs are characterized by the so-called 'blooming' effects for which areas of GRE MRI appear greater than the actual hemosiderin deposits. Despite some authors attempted to classify microbleeds with a maximum diameter from 2 to 10 mm [23], the available literature support the idea of the limited utility of size definition. Recently the use of higher resolution techniques such as three-dimensional GRE MRI, which is able to detect more CMBs than conventional one, supported the idea that different reported prevalences depend from the utilized methodology [24-26]. In fact microbleeds are paramagnetic and induce a susceptibility effect on MRI scan, depending from length of TE as well as their diameter and blooming effect [24]. However, several criteria for CMBs detections have been suggested [15]. CMBs prevalence has been also associated with severity of leukoaraiosis and lacunar infarcts [26]. Moreover, CMBs are considered a reliable predictor of future lobar hemorrhage and cognitive decline [27].

The location of CMBs may be helpful in determining the etiology of SVD since deep CMBs reflect hypertensive arteriopathy whereas lobar CMBs are more frequently associated with CAA [16]. Molecular imaging using PET amyloid ligands suggest that lobar CMBs preferentially occur at site of A β concentration [28].

PATHOLOGICAL FINDINGS AND PATHOPHYSIOLOGY

Different pathophysiological phases, which are mainly resumed in primary and secondary injury, have been described in ICH.

Primary Injury

ICH, which results from rupture of small penetrating arteries damaged by hypertension (hyalinosis, lipohyalinosis) or from rupture of pial branches in the case of cerebral amyloid angiopathy (fibrinoid necrosis), is generally surrounded by edema, but also inflammation and necrosis [29]. By mechanical compression hematoma may induce a disruption of the neuron and glia architecture, which in turn provides a blood flow neurotransmitter release impairment and a mitochondrial dysfunction [30-32]. This early phase correlates with initial clinical symptoms and signs.

Concomitantly the hemostatic cascade initiates and clot and hemoglobin breakdown products activate microglia, which in turn releases neurotransmitters inducing breakdown of the blood-brain barrier, vasogenic oedema, and apoptosis in neurons and glia. This phase correlates with hematoma expansion, which occurs in almost 73% of patients within 3-12 hours, and perihematoma oedema growth, which occurs within the first 24 hours from ICH onset. In this phase mitochondrial and metabolic dysfunction, as well as hypoperfusion phenomena, have been observed followed by a variable reperfusion phase from 2 to 14 days after ICH [33-37].

Secondary Injury

Secondary injury after ICH may be caused by different mechanisms, including: 1) direct complications of the hematoma mass effect such as hydrocephalus, 2) increased intracranial pressure leading to decreased cerebral perfusion and tissue shifts [4, 38] and 3) release of clot and inflammatory components (i.e thrombin, hemoglobin and iron), already initiated by the primary injury [4]. These factors may exert toxic effects on endothelial cells, neurons, astrocytes and microglia, contributing also to disrupt the blood brain barrier [39].

CAUSES OF ICH

Spontaneous ICH

The most important causes of spontaneous ICH are deep perforating vasculopathy and cerebral amyloid angiopathy.

Deep Perforating Vasculopathy

Nearly 50% of ICH is due to deep perforating vasculopathy, which results probably from reactive hyperplasia and microscopic degenerative changes of vessel wall components leading to reduced vascular reactivity and enhanced vessel wall fragility [40-41]. Deep perforating vasculopathy usually occurs in lenticulostriate arteries originating from middle cerebral artery as well as in small thalamic arteries arising from the posterior communicating and posterior cerebral arteries, and perforating vessels arising from the basilar artery. Spontaneous ICHs, which are due to rupture of small deep arteries, occur most frequently in the deep portion of cerebral hemispheres and the most common location are putamen (35-50% of cases),

subcortical white matter (30%) and cerebellum (16%). Pontine hemorrhages account for 5-12% of cases [40, 42]. In the past years hypertension related degenerative changes were believed to be the most important pathogenic mechanism. More recently other mechanisms involving environmental and genetic factors have been invoked [43]. One hypothetic pathogenic mechanism is that multiple acute or chronic risk factors, mostly sustained hypertension, interact with vulnerable damaged small vessels, leading ultimately to rupture and thus to ICH. However, a recent population based study reported that ICH might result from short-term increases in blood pressure prior to the event (over weeks to months), suggesting that blood pressure control may effectively reduce the risk of ICH [44].

Cerebral Amyloid Angiopathy

Sporadic cerebral amyloid angiopathy (CAA) accounts for at least 5% to 20% of all spontaneous ICH. It is characterized by the progressive deposition of amyloid β ($A\beta$) within the wall of small/medium size arteries and lesser in capillaries and veins in the leptomeninges of cerebral cortex [45-46]. This process, that preferentially affects cortical-subcortical regions, and rarely cerebellum and deep or brainstem structures, induces a thickening, focal fragmentation and disruption of small vessels, that sometimes is associated with microaneurismal dilatation and luminal occlusion [46-47]. Other neuropathological features associated with CAA, such as cortical microinfarcts and white matter hyperintensities, probably reflect reduced perfusion phenomena by CAA-affected arteries [48]. These aspects result in a wide spectrum of small vessels disease manifestations varying from asymptomatic lacunar lesions and cerebral microbleeds to symptomatic stroke, leukoaraiosis and ICH [13, 46]. Several evidences from pathological studies support the hypothesis that CAA has an important role in causing ICH [49-50]. A recent meta-analysis of published histopathological studies confirmed the association between CAA and lobar ICH (OR: 2.21; 95% CI: 1.09–4.45) [51]. A pathological study comparing brains with CAA and with and without ICH found that ICH subjects had a more severe CAA picture with fibrinoid necrosis in comparison to non-ICH subjects [51]. Microaneurysms occurred only in the presence of severe, rather than moderate or mild, CAA [52].

CAA has been described more frequently in elderly, in Eastern population [53-54] and does not seem to be associated with common cerebrovascular risk factors whereas anticoagulants and antiaggregants have been found to increase the risk of CAA related ICH [55-56].

The Boston criteria were proposed to estimate the likelihood of CAA in ICH. These criteria were mostly based on the site and number of hemorrhagic lesions on neuroimaging [57]. However, although these criteria have been widely used, some limitations due to the gap between the original analyzed sample (only symptomatic ICH) and the wide range of clinical and neuroradiological CAA findings were reported [51].

Secondary ICH

Several conditions have been identified as possible cause of ICH, and should be always considered in the diagnostic work up. They include brain injuries, primary and secondary neoplasms, aneurysms, arterio-venous malformations, cavernomas, coagulopathies, dural sinus venous thrombosis, vasculitis, Moya-Moya disease, brain irradiation and medications such as anticoagulants, thrombolytics, antiplatelets but also sympathomimetics and illicit drugs (cocaine, ecstasy amphetamines) (Table 1)

Table 1. Secondary causes of ICH

Traumatic
• <i>Immediate</i>
• <i>Delayed</i>
Aneurysm
Arterio-venous malformations
Cavernomas
Neoplasm with hemorrhage
• <i>Primary (glioblastoma, haemangioblastoma)</i>
• <i>Secondary (melanoma, histiocytoma, Grawitz's, lung, etc)</i>
Coagulopathies
Leukemia, DIC
Thrombocytopenia and other platelet disorders
Hemophilia and other hereditary coagulopathies
Hepatic failure
Renal failure
Dural sinus venous thrombosis
Artero-venous dural fistulae
Vasculitis
Vasculopathies
Dissections
Moya-Moya
Surgical procedures and interventions
Neurosurgery
AVM surgery
Craniotomy
Subdural haematomas burr-hole evacuation
Spinal surgery
Neuroradiological interventions
Carotid endoarterectomy
Carotid angioplasty
Cardiac transplantation
Brain irradiation
Sonothrombolysis
Medications
• <i>Anticoagulants, Thrombolytics, Antiplatelets</i>
• <i>Sympathomimetics, including over-the-counter pills and nasal sprays (ephedrine, pseudoephedrine and phenylpropanolamine)</i>
Alcohol
Illicit drugs (Cocaine, Ecstasy, Amphetamine)

Cerebral Arteriovenous Malformations (AVM)

VM are abnormal connections between arteries and veins, leading to arteriovenous shunting with the presence of the so-called “nidus” (network of vessels). The prevalence of AVM is between 15 and 18 subjects per 100 000 adults [58]. The overall detection of incidental AVM rate is 1 per 100 000 adults per year [59]. The first-ever hemorrhage rate is 0.55 per 100 000 person-years [59]. The hemorrhagic risk is higher (4.5%-34%) in previously ruptured brain AVMs (with deep venous storage and deeply seated); the risk is lower in unruptured brain AVMs (0.9%-8%) [60-61]. The risk of subsequent hemorrhage is higher in

case of: 1) deep venous drainage, 2) brain AVM presentation with hemorrhage, 3) association with aneurysms, 4) deep location [61-62].

Cavernous Malformations (CMs)

Cavernous malformations (CMs) consist of endothelium lined dilated spaces with deficiency in both the smooth muscle layer and the tight junction and with occurrence of thrombosis and calcification. Prevalence of CMs is 0.4–0.6% [63-64]. CMs account for approximately 5%–10% of all cerebral vascular malformations, and roughly 20% of them are located in the brainstem [64-65]. Most CMs remain clinically quiescent. CMs located in neurologically eloquent areas are prone to become symptomatic often with seizures due to the microscopic accumulation of hemosiderin in susceptible cortex. CMs can be sporadic or hereditary. CMs can cause extra-lesional hemorrhage (beyond the confines of the cavernoma) or intra-lesional hemorrhage (within the cavernoma itself). In patients managed conservatively hemorrhage risk varies between 0.25% and 4.5% per person/year [64]. The overall risk of first hemorrhage in familial cases is 1.4% per person/year. The risk of recurrent hemorrhage after a first intracerebral hemorrhage has been evaluated from 3.8% to 33.9% per year [64]. In brainstem CMs an annual secondary hemorrhage rate of 5.1% has been found in patients not receiving treatment [64-65].

Moyamoya Disease (MMD)

Moyamoya disease (MMD) is a chronic occlusive cerebrovascular disease involving progressive stenosis of the terminal portion of the internal carotid arteries and/or the proximal portions of its main branches, associated with the development of fine collateral networks, especially adjacent to the site of occlusion in the deep areas of the brain. This last feature, detectable on dynamic angiography, was originally described in the Japanese literature as ‘moyamoya,’ which translates into English as “a puff of cigarette smoke” [66-67]. MMD is a rare disease more frequently occurring in Asian countries, particularly in Japan where an incidence up to 0.54 per 100000 has been reported. However, although MMD has been described in all races and ethnicities worldwide, limited data are available in Western countries, where the incidence rate is probably about ten times lower (about 0.086 per 100000) than in Asia [68-69], and it probably remains a misdiagnosed cause of ischemic or hemorrhagic stroke.

Cerebrovascular events are the main presenting symptoms and are related both to the stenosis and occlusion of the ICAs (transient ischemic attack, ischemic stroke) and to the rupture of fragile collateral vessels (hemorrhagic stroke). In the Japanese literature, opposed to what observed in US, the ischemic type has been shown to predominate in childhood, while the hemorrhagic type is more often observed in the adult population. In Western countries ischemic events seem predominate both in children and in adult patients [70-74]. In adult MMD intracerebral hematomas are more often associated with intracranial aneurysms, ACA occlusion, fetal-type PCA, MCA occlusion with collateral flow, whereas ACA occlusion was mostly associated with deep intracerebral hemorrhage or IVH [75-76]. Independent risk factors for hemorrhage are anterior choroidal artery and posterior communicating artery dilation [75], cerebral microbleeds mostly near the midline structure or in deep brain areas. The annual risk for stroke (hemorrhagic or ischemic) is 3.2% per year in asymptomatic Moyamoya patients [76]. In symptomatic Moyamoya patients, the 5-year risk of recurrent ipsilateral stroke is 65% if medically treated, and 17% in the group admitted to

surgery [76]. In the Japanese population, during a 5-year follow-up in hemorrhagic Moyamoya, rebleeding attacks were observed in 11.9% and in 31.6% of patients who were surgically and conservatively treated, respectively [77].

GENETICS OF ICH

Single-Gene Disorders

A number of monogenic disease may predispose to cerebral hemorrhage with two main mechanisms: 1) favoring the development of macroscopic vascular malformation such as mutations in the malcavernin and KRIT1 genes associated with CCM1 and CCM2 or in the ENG gene and other loci associated with Hereditary Hemorrhagic Telangiectasia (HHT) 2) causing cerebral hemorrhage in the context of a more complex picture of small vessels disease such as Hereditary Cerebral Amyloid Angiopathy and mutations in COL4A1 gene and, less often, in NOTCH3 gene, associated with CADASIL [78].

Cerebral Cavernous Malformation (CCM)

Cerebral cavernous malformations (CCMs) consist of abnormally enlarged capillary cavities in the absence of intervening brain parenchyma. Three genes have been recognized as responsible of heritable CCM: KRIT1 (CCM1;OMIM 604214-116860), CCM2/malcavernin (CCM2; OMIM 607929) and PDCD10 (CCM3;OMIM 609118). The pattern of inheritance is autosomal dominant. The most common clinical symptoms are seizures, cerebral hemorrhage, focal neurological deficits and headache with onset around thirty years [79] with an earlier occurrence of Haemorrhagic symptoms [79].

Hereditary Hemorrhagic Teleangiectasia (HHT)

The disease is characterized by the presence of multiple arteriovenous malformations (AVMs) that lack intervening capillaries and result in direct connections between arteries and veins. It is a genetically heterogeneous condition with an autosomal dominant pattern of inheritance and age-related penetrance. So far a number of different genes have been identified such as endoglin (ENG) gene (OMIM 187300-131195) on chromosome 9q34.11, activin A receptor type-II like 1 (ACVRL1) gene (OMIM 600376-601284) on chromosome 12q13.13 and SMAD4 gene (OMIM 175050-600993) on chromosome 18q21.2. The main clinical findings are epistaxis, gastrointestinal bleeding, telangiectasia, pulmonary and hepatic AVMs. Central nervous system involvement occurs in about 10% of cases [80].

Hereditary Cerebral Amyloid Angiopathy (H-CAA)

1) APP-Related CAA (OMIM 605714-104760)

The APP gene, located on chromosome 21q.21.3, encodes for amyloid precursor protein (APP; 104760). Mutations in the APP gene cause abnormal deposition of A-beta peptide.

Hereditary cerebral hemorrhage with amyloidosis–Dutch type (HCHWA-D) is an autosomal dominant form of CAA due to a point mutation at codon 693 of the A-beta precursor protein gene (glutamine for glutamic acid substitution at position 22 of A-beta.

Mutation carriers develop diffuse white matter changes, brain hemorrhages and ischaemic strokes. Dementia is common after 40 years and is associated with extensive amyloid-induced vasculopathy affecting cortical vessels independently of neurofibrillary tangles or plaques [81-82]. Typical neuropathological findings consist of diffuse amyloid fibril depositions in the wall of cerebral and leptomeningeal small and medium size vessels with limited neurofibrillary degeneration and in the absence of classical dense core A-beta plaques [83]. Severe pathological features of CCA with or without neurofibrillary pathology have been observed in the Italian (E693 K), Arctic (E693G), Iowa (D694 N) and Piedmont variants (L705 V) [84]. The Flemish mutation (A692G) results in a phenotype characterized by early onset AD or cerebral hemorrhage with neurofibrillary tangles and AD-type parenchymal plaques centered on blood vessels [84].

2) Cystatin-Related (CST3), Icelandic Type, CAA (OMIM 105150-604312)

HCHWA-I is an autosomal dominant form of CAA resulting from mutations (A to T point mutation causing a glutamine for leucine substitution) in the cystatin C gene on chromosome 20p11.2. The clinical picture is characterized by early onset ICH and dementia. ICHs are often multifocal and are more likely to occur in previously healthy and normotensive subjects [85-86]. Cystatin is produced by neurons and other CNS cells and is an inhibitor of extracellular cysteine protease [86]. The amyloid protein isolated from leptomeninges of affected patients starts at position 11 of normal cystatin C and has an amino acid substitution, Leu to Gln, at position 68 (L68Q) leading to a change in some physical properties of the protein resulting in accelerated cerebrovascular amyloid deposition [87]. Pathological studies reveal widespread deposition of amyloid resulting from degradation products of mutated cystatin C in leptomeninges and brain, but also in peripheral tissues such as skin, lymphoid organs, salivary glands and testes [87-88].

3) TTR-Related CAA (OMIM 105210)

TTR related amyloidosis are a genetically and phenotypically heterogeneous group of autosomal dominant clinical entities due to mutations on the TTR gene on chromosome 18. Systemic involvement includes polyneuropathy, carpal tunnel syndrome, autonomic insufficiency, cardiomyopathy, and gastrointestinal features, less frequently accompanied by vitreous opacities and renal insufficiency [88-89].

A distinct form of TTR-related amyloidosis with predominant CNS involvement is leptomeningeal amyloidosis. The main clinical features are dementia, seizures, strokes and visual impairment secondary to vitreous amyloid deposition. Hagiwara et al. (2009) reported a patient with progressive polyradiculoneuropathy, ataxia and hearing loss who developed lethal multiple cerebral hemorrhages [90]. Diffuse amyloidosis involving leptomeninges and subarachnoid vessels associated with patchy fibrosis and obliteration of the subarachnoid space were evident on pathologic examination. Associated findings were severe and diffuse neuronal loss and generalized subpial gliosis and occasional superficial brain infarcts [91].

COL4A1 Syndrome (OMIM 605595-120130)

Type IV collagen is a major component of basement membranes consisting of six homologous, but genetically distinct, α chains that are selectively expressed in different membranes and at different stages of embryonic development [92]. COL4A1 gene, consisting of 52 exons, is located on the telomeric region of chromosome 13q (13q34) by Solomon et al.

(1985) and Emanuel et al. (1986) [93-94]. Mutations in the collagen IV genes are associated with reduced stability and defects of the basement membrane. The resulting phenotype is consistent with a systemic small vessel disease with recurrent brain involvement. Mutations in the collagen IV alpha chain 1 (COL4A1) gene are known to be associated with a highly variable phenotype consisting of familial porencephaly, migraine with and without aura, infantile hemiparesis, seizures and perinatal intraventricular hemorrhages [95-97]. Clinical features of small vessel disease of the brain are quite common findings. Stroke occurs in 17.3% of subjects with a mean age at onset of 36.1 (range 14-40 yrs.). The most part is hemorrhagic (67%) whereas all the ischaemic strokes are lacunar (33%).

COL4A1 gene has been recently associated with sporadic ICH [97]. In a cohort of 96 patients with sporadic ICH (48 deep and 48 lobar ICH) COL4A1 gene has been sequenced and 2 rare nonsynonymous variants were found. It has been proposed that altered COL4A1/2 secretion may contribute to sporadic cerebrovascular disease and ICH [97].

Candidate Gene Variants Associated with Intracerebral Hemorrhage

As for other complex diseases, a number of polymorphisms, mostly implicated in vascular wall integrity (i.e APOE, ACE, neprilysin, endoglin, TGF β 1), endothelial function (i.e ACE), vessel wall reactivity or coagulation (i.e APOE, CD-14, Factor VII, XIII, VKORC1) have been investigated as potential risk factors for sporadic cerebral hemorrhage, using the candidate-gene approach. However, due to some methodological problems the results of these studies are controversial and were not robustly replicated [78].

Vessel Wall Integrity

APOE (locus 19q13.2): Apolipoprotein E is a glycoprotein that plays an important role in the lipid transport and metabolism, in the cellular membrane stability and reparation and it is significantly expressed in the brain. Moreover, ApoE plays a critical role in several other processes, such as neuronal damage reparation, maintenance of synaptic plasticity, mitochondrial resistance to oxidative stress and the use of glucose in neuronal and glial cells.

The well-known relationship between APOE and Alzheimer's disease (AD), which is strictly associated to cerebral amyloid angiopathy CAA (80% of subject affected by AD show some evidence of CAA), led to a growing interest in studying the APOE frequency in patients with CAA-ICH.

Apolipoprotein E gene, mapped on chromosome 19, encodes for a glycoprotein, ApoE, with three common isoform E2, E3, E4, codified by ϵ 2, ϵ 3, ϵ 4 alleles, whose frequency in Caucasian population are, respectively, 7,3%, 78,3% e 14,3% [98]. These three different allelic forms (ϵ 2, ϵ 3, ϵ 4) differ for a cysteine/arginine polymorphism in 112 and 158 positions and can generate 6 different genotype; ϵ 3/ ϵ 3 genotype is the most represented and is present in about 50-75% of the population.

Many studies have been carried out aimed at investigating the role of APOE polymorphism in Haemorrhagic stroke, with contrasting results.

Greenberg et al, in 1996 [99] firstly demonstrated the association between ApoE ϵ 4 and pathologically proven or suspected cases of cerebral amyloid angiopathy, as well as with an earlier onset of lobar hemorrhage. They also demonstrated that ApoE ϵ 4 is neither necessary nor sufficient for the occurrence of CAA-related hemorrhage. In fact the vast majority of

subjects carrying this allele in general population do not show clinical CAA. Otherwise other studies [100-101] demonstrated the association between ApoE $\epsilon 2$ and not $\epsilon 4$ allele and ICH and lobar hemorrhage.

Both these ApoE alleles would seem to increase the risk of CAA, and are also associated with the occurring of the first Haemorrhagic event at a young age and a higher recurrence rate. According to Greenberg (1998) [99] and Nicoll (2001) [101] ApoE $\epsilon 4$ acts in CAA by promoting amyloid deposition. ApoE $\epsilon 2$, instead, is not associated with amyloid deposition, but rather to degenerative changes, such as fibrinoid necrosis, which leads to breakage of those vessels in which the amyloid is deposited. Considering these mechanisms, these two alleles appear to have a complementary role in CAA progression. Sudlow et al. 2006 [102] reported that ApoE $\epsilon 2$ was associated with the occurrence of ICH (OR1.32; 95% CI 1.01-3.87) and the association was particularly strong for lobar hemorrhage (OR 2.37; 95% CI 1.45-3.87). Recently, in a three-phase study (one discovery and two replication studies), Biffi et al. in 2011, [103] demonstrated that individuals carrying ApoE $\epsilon 2$ and ApoE $\epsilon 4$ alleles had lobar hemorrhage, but only ApoE $\epsilon 2$ was associated with lobar ICH volume (mean increase 5.3 mL; 95% CI 4.7-5.9) and poor outcome (OR 1.68; 95% CI 1.10-2; $p=0.009$) and mortality (OR 1.60; 95% CI 1.13-2.25; $p=0.008$). The generally accepted explanation is that ApoE- $\epsilon 4$ promotes vascular amyloid deposition, while ApoE- $\epsilon 2$ promotes progression to severe CAA with associated vasculopathic changes, which cause vessel rupture and ICH [104]. ApoE $\epsilon 2$ allele was also found to be correlated with leukoencephalopathy, but neither $\epsilon 2$ nor $\epsilon 4$ allele seems to be related to the presence of microbleeds on MRI [105]. A study on 41 elderly patients with warfarin-associated cerebral hemorrhage showed a higher frequency of $\epsilon 2$ carriers, especially in patients with lobar ICH [106].

ACE (Locus 17q23) and α -ADDUCIN (Locus 4p16.3)

The angiotensin-converting enzyme (ACE) is a dipeptidyl carboxypeptidase that catalyzes the formation of angiotensin II from angiotensin I and of bradykinin [107]. Both these substances are mediators of vascular tone and are involved in smooth muscle cell proliferation, in vascular remodeling and in atherosclerosis. Angiotensin II is a potent vasoconstrictor involved in vascular hypertrophy, thrombosis and vessel wall damage [108]. Human ACE gene contains 26 exons and is localized on the chromosome 17. Studies on human ACE gene identified a polymorphism that consists on the presence (insertion, I) or absence (deletion, D) of a 250 base-pairs fragment in intron 16, whose presence or absence influences the enzyme activity, with the DD genotype correlated to a greater activity, the II genotype to a lower activity and the ID genotype to an intermediate one.

So far there are no convincing data on the role of ACE gene I / D polymorphisms as a risk factor for spontaneous intracerebral hemorrhage. Two studies on Asiatic, Japanese and Taiwan population yielded negative results whereas a polish study reported a positive association between ICH and ACE gene [109-111].

In an Indian study conducted in 2011, the ACE DD genotype, alone or in association with a single nucleotide polymorphism, providing the substitution of tryptophan in place of a glycine of Alfa-adducin (ADDI), was associated with spontaneous ICH, especially not lobar [112]. The presence of DD genotype showed a risk of ICH 7.4 times higher than wild genotype (OR 7.04, $P 0.001$). The presence of D allele was significantly associated with ICH compared to I allele.

Coagulation System

Factor V Leiden (Locus 1q23) and Prothrombin 20210A (Locus 11p11-q12)

A missense mutation in codon 506 of the factor V gene (called FV Leiden) was associated with resistance to activated Protein C (APC). This molecular variant creates a prothrombotic state, which is believed to be a risk factor for venous thrombosis. Subjects with factor V Leiden molecular variant had decreased risk for spontaneous intracranial hemorrhage (odds ratio, 0.19; 95% confidence interval, 0.03-0.95)(118). Prothrombin 20210A/G is another frequent prothrombotic single nucleotide polymorphism (SNP), which was associated with reduced risk of ICH in comparison to controls (1.5% vs 3%, respectively) [113].

Factor VII (Locus 14q34)

Factor VII plays an important role in coagulation system and its deficiency is associated with bleeding disorders. The congenital deficit of this protein has been observed to predispose to spontaneous (including intracranial) and post-surgical bleeding. It has been suggested that a polymorphism conditioning the insertion/deletion of 10 base pairs in position 323, that is associated with lower levels of factor VII, could predispose to cerebral hemorrhage [113]. However, the available data are not sufficient to draw significant conclusions.

Factor XIII (Locus 6p25.1)

Coagulation factor XIII is a transglutaminase, which plays an important role in the clot stabilization through the crosslinking of fibrin chains, in matrix remodelling, cellular adhesion and migration and tissue repair. Congenital factor XIII deficiency is a hereditary bleeding disorder caused by reduced levels and activity of factor XIII, which is characterized by bleeding diathesis with a clinical manifestation often including intracranial hemorrhage. Studies on sporadic cerebral hemorrhage revealed that a point mutation G → T in exon 2 codon 34 of the gene encoding the A subunit of FXIII, which involves the replacement of a Leucine with a Valine (FXIII Val34Leu), seems to increase the risk non-traumatic cerebral hemorrhage [114-115].

However, the role of FXIII Val34Leu is controversial since other studies and the meta-analysis of Peck et al. [116-117] did not confirm the association between this molecular variant and ICH.

Serpin 3 (Locus 14q32.1)

SERPIN 3 gene (formerly known as α 1-antichymotrypsin) encodes a protease inhibitor protein, which could prevent the degradation of extracellular matrix in the vessel wall. In a study on the Spanish population the association between the A/T polymorphism in SERPIN 3 gene and cerebral hemorrhage has been reported in normotensive patients [118-119]. Conversely a Polish study did not find any association between the SERPIN 3 A/T polymorphism and the risk of cerebral hemorrhage [120]. Although ethnic differences in genetic background and in susceptibility to cerebral hemorrhage may explain the heterogeneous results, available studies are not enough convincing to get any significant conclusion.

MTHFR (Locus 1p36.3)

The methylenetetrahydrofolate reductase (MTHFR) is an enzyme involved in the transformation of 5,10-methylenetetrahydrofolate to 5-methyltetrahydrofolate, which acts as a methyl donor for methylation of homocysteine to methionine, through the intervention of vitamin B12. The homocysteine metabolism is partially determined by common SNPs in the MTHFR gene, such as C677T and A1298C, which seem to have a role as risk factors for stroke. Some studies have reported that high plasma levels of homocysteine are associated not only with ischemic stroke, but also with cerebral hemorrhage [121-123], by effects on coagulation and by rupture of microaneurysms. In any case, data relating the role of homocysteine and MTHFR genotype in Haemorrhagic stroke are currently few and have low significance. Peck et al, in 2008 [117] found a weak association between MTHFR 677TT genotype and hemorrhagic stroke within overall OR of 1.11 (95% CI 0.89-1.39). A recent prospective study showed that both hyperhomocysteinaemia and MTHFR 677 T allele are independent risk factors for hemorrhagic stroke in the Swedish population [124]. Other explored factors involved in the coagulation system such as Serpin 1 (locus 14q32.1), Endoglin (locus 9q34.1), Glycoproteins Ia (5q11.2), IIIa (17q21.32) and Ib α (17p13.2) Perilipin (locus 15q26) were not associated with the risk of ICH [78, 117].

Inflammatory Markers

Since inflammatory response plays an important role following ICH, and release of inflammatory cytokines increases blood-brain barrier permeability, cerebral oedema and secondary neuronal injury, a number of candidate gene involved in inflammatory process was studied.

TNF (6p21.3 Locus)

The Tumor Necrosis Factor α is one of the main proinflammatory cytokine and plays a central role in initiation and regulation of the inflammatory response. Increased values of serum TNF were associated with an increased rate of mortality after ICH and recurrent stroke. A study conducted on Taiwan population investigated the possible role of four SNPs in the promoter region of this gene (T-1031C, C-863A, C-857T, and G-308A) in predisposing to deep brain hemorrhage or influencing the outcome at 30 days [115]. The study demonstrated a weak association between these variants and the risk and the size of ICH.

IL-4 (Locus 5q31.1)

Interleukin-4 (IL-4) is a member of the T helper 2 (Th2) cytokines and its role is to reduce the production of pro-inflammatory cytokines and destructive enzymes by monocytes [126]. IL-4 polymorphisms (rs2243250, rs2070874) were analyzed in Korean patients with intracerebral hemorrhage (ICH) [127]. In this study, IL-4 gene polymorphisms [rs2243250 (promoter 524T/C) and rs2070874 (5-UTR, 33T/C)] were associated with ICH by lowering IL-4 levels and its neuroprotective effect [128].

IL-6 (Locus 7p15.3)

IL-6 plays a key role in promoting acute inflammatory response and regulating the production of acute phase proteins such as C-reactive protein. In addition, it contributes to the inflammatory response by activating endothelial cells and stimulating the synthesis of

fibrinogen. It has been demonstrated that the 572G → C polymorphism is significantly associated with the risk of cerebral hemorrhage [130]. Another polymorphism within the same gene (174G → C) was found to be associated with cerebral hemorrhage secondary to an arteriovenous malformation [130]. It was also demonstrated that high IL-6 levels are a predictive factor of increased hematoma volume in the acute phase [131]. These observations suggest that IL-6 is important both in onset and in the evolution of cerebral hemorrhage. The local release of IL-6 could contribute to vascular wall instability by stimulating the release and the activation of matrix metal-proteinases (MMPs).

ALOX5AP (Locus 13q12.3)

Among eicosanoid biosynthesis genes (ALOX12, ALOX5, ALOX5AP, PTGES, PTGIS, PTGS1 and PTGS2) ALOX5AP was found to be associated with stroke and to contribute to ICH susceptibility in Korean population [132]. In this study, the G allele frequency of rs17222919 in the ICH group was about 3.8-fold (86.7%) than controls. These results suggest that the G allele may be a risk factor for the development of ICH.

Complement Cascade

Common genetic variants in the key components of complement pathway have been associated with greater inflammation and cerebral injury after ICH. A prospective cohort study was implemented to investigate the relationship between SNPs in complement component 3 C3 (rs2230199, R102G, C/G), complement component 5 C5 (rs17611, I802V, A/G) and Complement Factor H (rs1061170, Y402H, T/C) genes and mortality after ICH [133]. Complement Factor H (CFH) inhibits pathologic activation of the inflammatory cascade, and thus cellular damage. Functional genetic variants in CFH can result in aberrant CFH activity, leading to abnormal activation of the complement cascade, greater degrees of inflammation in the perihematoma zone, and worse brain injury and outcome. Genetic variation in CFH, in particular the Y402H polymorphism, was significantly associated with both discharge ($p = 0.01$) and 6-month mortality ($p = 0.02$) after spontaneous intracerebral hemorrhage, whereas this association was not observed for C3 ($p = 0.545$ and $p = 0.830$) or C5 ($p = 0.983$ and $p = 0.536$) SNP.

PDGF-D (Locus 11 q22.3)

Platelet-derived growth factor D (PDGF-D) plays an important role in angiogenesis, vessel remodelling, inflammation and repair in response to injury. The -858AA genotype associated with higher risk of first-ever ICH in non-hypertensive cases, as well as reduced incidence of recurrent ICH [134]. This effect may be explicated by the angiogenic and wound healing effects of PDGF-D.

TP53 (Locus 17 p13.1)

TP53 encodes for a tumor suppressor protein, which mediates apoptosis (p53). The presence of apoptotic neurons in the area surrounding hematoma in hemorrhagic strokes may be a cause of reduced recovery. Several SNPs have been identified within the TP53 gene, both in the coding and in the non-coding region. One of the most studied is a single nucleotide polymorphism in codon 72 (exon 4) with an arginine-proline substitution (Arg72Pro) in a domain involved in the preapoptotic function of p53. The Arg72 variant of

p53 enhances the properties of the proapoptotic protein and inhibition of oncogenesis compared to variant Pro72. It was recently demonstrated an association between the genotype Arg/Arg and a poor prognosis after ischemic or hemorrhagic stroke. This genotype was also correlated with an increased volume of the cavity resulting from cerebral hemorrhage. The *in vitro* Arg72-p53, but not the Pro-p53, interacts directly with mitochondrial Bcl-xL and activates the apoptotic intrinsic pathway, increasing the vulnerability to apoptosis induced by ischemia. These results suggest that the TP53 genotype Arg/Arg influences the neuronal vulnerability to apoptosis and may be a genetic marker of poor outcome following an ischemic or hemorrhagic stroke [135].

Tubulin β 1 (Locus 20b q13.32)

Platelets play very important functions in hemostasis and atherothrombosis. Genetic alterations in platelet receptor proteins have been studied as potential risk factors for thrombotic events or bleeding. The β 1-tubulin is expressed in platelets and in megakaryocytes and, together with α -tubulin, forms heterodimers that are assembled in microtubules polymers. It has been demonstrated that the β 1-tubulin is essential for platelets formation although the exact mechanism by which the β 1-tubulin participates in platelet aggregation has not yet been elucidated. A TUBB1 Q43P polymorphism has been observed to increase the risk of cerebral hemorrhage. The platelet hyporeactivity in carriers of this allele may be particularly relevant in patients taking antiplatelet drugs such as aspirin. It has been observed that the presence in the same subject of TUBB1 Q43P and FVII 323 Del/Ins polymorphisms increases the risk of developing cerebral hemorrhage of about 20 times, suggesting that the combination of low factor VII plasma levels with reduced platelet activation could have dramatic effects. Also the association with the FXIII L34 allele increases the risk of developing ICH, through the association of a defect of platelet aggregation and a decreased stability of the clot [136].

CR1 (Locus 1q32.2)

A genome-wide association study conducted in order to investigate the genetic risk factors for sporadic AD demonstrates that a variant within the CR1 gene (single nucleotide polymorphism rs6656401) increases the risk for Alzheimer disease (AD). Given the pathological overlap between AD and CAA-related ICH, Biffi et al. [137] recently performed a case control study in order to determine whether this polymorphism also influences the risk of developing clinically symptomatic CAA-related ICH, as well as histopathological severity of CAA. They found out an association of the A allele of rs6656401 at the CR1 locus with the risk of CAA-ICH (OR 1.61, 95% CI 1.19–2.17, $p = 8.0 \times 10^{-4}$), the risk of recurrent CAA-ICH (HR 1.35, 95% CI 1.04–1.76, $p=0.024$), and the severity of CAA pathology at autopsy (OR 1.34, 95% CI 1.05–1.71, $p=0.009$). According to this study, CR1 would seem to increase the risk of both AD and CAA acting independently on vascular and parenchymal amyloid deposition.

Chapter 26

ANIMAL MODELS OF STROKE: PRESENT AND FUTURE

B. Casolla, S. Candela, A. Ciacciarelli and F. Orzi*

NESMOS (Neurosciences, Mental Health and Sensory Organs)
Department, University “Sapienza” of Rome, Italy

ABSTRACT

Animal models have greatly contributed to our understanding of the risk factors and the pathophysiology of stroke, as well as the development of therapeutic strategies for its treatment. Further development and investigation of experimental models, however, are needed to elucidate the pathogenesis of stroke and to enhance and expand novel therapeutic targets. In this chapter, we provide an overview of the characteristics of commonly-used animal models of stroke, which may provide insights into a framework for developing effective therapies for stroke in humans.

Keywords: animal model; stroke; ischemia; neuro-inflammation.

INTRODUCTION

Over the last four decades, a variety of animal stroke models have been developed, with the aim of identifying the pathophysiologic mechanisms that underlie cerebral ischemia and developing new agents for stroke therapy. Several ischemic stroke models have been developed in a variety of species; these include mechanical occlusion of the middle cerebral artery (MCA), thromboembolic models, and photothrombotic models.

This chapter focuses on models of global and focal cerebral ischemia by means of vessel occlusions.

VESSEL OCCLUSIONS

Because brain function depends on cerebral blood flow (CBF) for continuous supply of energy metabolism, brain ischemia can be modeled by occlusion of a cerebral arterial vessel.

The residual CBF caused by vessel occlusion can be graded according to two major variables: time and space. Time refers to the duration of the occlusion. Space refers to the extent of the lesion, according to the site of the occlusion. There are, therefore, models of temporal or permanent occlusion, and models of focal or global ischemia models. While global ischemia is consistently associated with a temporal occlusion of bilateral large vessels of the neck, focal lesions distribute along a continuum, which ranges from very short to permanent occlusions affecting small or large brain volumes. The extent of the ischemic lesion depends on whether the occlusion is proximal or distal. Occlusion of the vessel is obtained by mechanical or biochemical means. Direct mechanical occlusion include ligation or clipping, or insertion of a silicon-coated nylon threads into the internal carotid artery that is subsequently advanced to the target vessel. In order to mimic thromboembolism, macrospheres or autologous blood clots are injected directly into the internal carotid artery. Local injection of purified thrombin or of vasoconstrictor substances (such as endothelin-1 in the rat) may cause reproducible focal lesions. Pros and cons of these approaches have been described in several reviews [1] and the choice of a model reflects the balance between reproducibility, similarity with pathophysiology of stroke, easiness and brevity of the approach, extent of surgery and anesthesia (Table).

Global Ischemia

Global, permanent brain ischemia causes irreversible whole brain damage and death. Reversible, temporary global ischemia, such as it occurs in humans during cardiac arrest and resuscitation, is a transient loss of blood flow to the entire brain. If the global ischemia is short enough the brain tissue survives the insult, but parts of the tissue or nervous cells may eventually die, hours or days following the insult. The phenomenon is modeled by the classic 2-vessel occlusion in the gerbil. Bilateral occlusion of the carotids in the gerbil causes marked, diffuse reduction of CBF. A long lasting (approximately more than 15 minutes) occlusion causes death. Shorter occlusions may appear asymptomatic or result in minor behavioral disorders. Typically, following 5-minute occlusion the animals show no evident motor or behaviour deficit, to eventually develop in the days following the occlusion a focal lesion in the CA1 section of the hippocampus. Remarkably, CBF returns back to normal a few minutes after the release of the occlusion. Thus the pathogenic process that would end in cell death occurs under conditions of normal CBF. Two phenomena, therefore, characterize the 2-vessel 5-minute occlusion in the gerbil: 1) an interval of time during which there is no structural change before the damage becomes apparent 2-4 days following recirculation (maturation phenomenon); 2) a focal distribution of the damage in spite of the whole brain ischemia (selective vulnerability). The finding indicates that intrinsic tissue factors contribute heavily to the damage. Severe hypoxia or hypoglycemia may also produce brain injury in specific brain areas, consistently with the notion that local variables, other than blood flow, are relevant in determining the vulnerability to the energy deprivation.

Table 1. Advantages and limitations of rodent models of focal and global cerebral ischemia

	<i>Advantages</i>	<i>Limitations</i>	<i>Experimental procedure</i>
<i>Focal ischemia</i>			
Craniotomy	High long-term survival rates; Visual confirmation of successful MCAo	Invasiveness; High degree of surgical skill	Direct surgical MCAo requiring craniectomy and section of the dura mater to expose MCA
Endothelin-1 (ET-1)	Non invasive	Variability of magnitude and duration of ischemia; Astrocytosis and axonal sprouting; Not suitable for thrombolysis studies	Direct application of vasoconstrictor ET-1 to MCA
Embolic stroke	Similarity with pathogenesis of human stroke; Appropriate for studies of thrombolytic agents	Variability of lesion size; Low reproducibility; Spontaneous recanalization	Injection of autologous blood or artificial clots into ICA
Intraluminal suture	Non invasive; Suitable for transient and permanent ischemia	Risk of post stroke hyperthermia or subarachnoid hemorrhage	Filament advanced via the ICA to occlude MCA
Clip/mechanical device occlusion model	Control of occlusion site; Reproducible infarcts; Suitable for transient or permanent ischemia; Low mortality	Invasive	Clipping of MCA
Photothrombosis	Non invasive; Reproducible infarcts	Infarct size usually small; Not suitable for ischemia in clinically relevant arterial territory (MCA)	Injection of photoactive dye; Laser irradiation of cerebral cortex; Microvascular coagulation in irradiated area
<i>Global ischemia</i>			
2 vessel occlusion in the gerbil	Easy to perform; Non invasive	Model of cardiac arrest	Bilateral occlusion of CCA
4 vessel occlusion in the rat	Easy to perform	High mortality rates; Uncertain complete occlusion of vertebral arteries	Electrocauterization of vertebral arteries and after 24 hours bilateral occlusion of the CCA

MCA: Middle Cerebral Artery; MCAo: MCA occlusion; ICA: Internal Carotid Artery, CCA: Common Carotid Artery.

The report of the phenomenon [2, 3] has boosted research in the field, as it became evident that ischemic damage is not just a sudden event causing necrosis. It can be a process triggered, but not sustained, by the initial ischemic insult. In general, the length of the maturation process is related to the intensity of the insult: the stronger the insult the shorter the delay in the development of the structural damage. The ischemic damage of the CA1 hippocampus associated with 5 min bilateral carotid occlusion in the gerbil is prevented by 2+2 min occlusion (*per se* not deleterious) carried out at 48 h interval before the 5 min occlusion [4]. The 2+2 min occlusion serves as a subliminal ischemic insult, which induces tolerance to ischemic injury. It is the result of the activation of endogenous adaptive mechanisms, which follow the exposure (preconditioning) to a stressful, but non-damaging, stimulus. Ischemic tolerance can be acquired by several stimuli including short episodes of transient focal and global cerebral ischemia, remote organ ischemia, hypoxia, hypothermia, hyperthermia, exposure to inhalation anesthetics, cortical spreading depression, brief episodes of seizures or by exposure to low-dose bacterial lipopolysaccharide prior to cerebral ischemia [5–7].

Bilateral occlusion of the common carotid arteries in the young-adult rats is without any apparent acute, or sub-acute pathogenic effect. The condition is instead thought to model the chronic hypoperfusion frequently observed in aging and neurocognitive progressive disorders [8]. Thus, the so-called 2-vessel occlusion model in the rat has been employed to examine the role of cerebral hypoperfusion in neurodegenerative processes [9]. A similar model was developed in the mouse by positioning microcoils in both carotid arteries [10]. Occlusion of the arteries causes decrease of CBF to 35–45% of control in cortical areas and to about 60% in the hippocampus and subcortical areas. A partial recovery of the flow occurs in the days following the occlusion with an almost complete recovery in 2–3 months. After 6 months the flow has completely recovered in the study by Choy et al. [11]. The cerebral glucose utilization seems to follow the reduction in CBF, with an initial delay and a more rapid recovery [12, 13]. Thus, the 2-vessel occlusion animals show an initial acute CBF reduction followed by progressive recovery. The progressive restitution to normal flow, therefore, encompasses a phase of chronic oligoemia, associated with reduction of glucose metabolism. Such a phase lasts for 2–3 months following vessel ligation. Because of such long-lasting recovery, the pattern of blood flow changes is inconsistent with the constant or progressive cerebral hypoperfusion observed in aging and dementia. In order to model the chronic blood flow derangement, gradual occlusion of the carotids with a device that constricts over time has been used [14].

In spite of such a limit, the chronic oligoemia is thought to model the chronic hypoperfusion observed in humans, and to cause similar structural and functional brain changes. The 2-vessel occlusion rats show behavioral changes, which share similarities with the cognitive disorders in humans. The animals show impaired spatial and non-spatial memory and fear conditioning [9]. The behavioral alterations are measurable a few weeks following occlusion and seem to progress with time in spite of the recovery of the blood flow. The progression is with the hypothesis that most of the changes occur during the chronic phase of the hypoperfusion, consistently with the hypothesis of a neurodegenerative-like mechanism sustained by the long-lasting hypoperfusion.

Focal Ischemia

Focal, permanent, or long lasting, occlusion of an intracerebral vessel causes necrosis, which coexists with brain areas of altered function, containing damaged, yet viable, cells. In a classical experimental setting [15, 16] clipping of middle cerebral artery in the baboon, during anesthesia, causes drop in regional CBF, subsequent moderate elevation of extracellular K⁺, extracellular acidosis and decline in evoked potential amplitude. By varying systemic blood pressure, and hence regional CBF, the authors were able to establish the interrelations occurring among regional CBF, evoked potential, extracellular K⁺ and pH. Reduction of CBF to approximately 15 ml/100gm per minute (approximately 35% of control) in the baboon leads to complete failure of the somatosensory evoked response. Lower rates of CBF were associated with massive release of intracellular K⁺ (as detected by intra-cerebral electrodes), a condition likely reflecting cell death. Thus, different low levels of regional CBF were associated with different biochemical and functional consequences. Essentially, two CBF thresholds were identified in ischemia: the lower threshold for release of K⁺ (necrosis), and the higher threshold for electrical failure (dysfunctional, viable cells).

The findings introduced the concept of ischemic penumbra, defined as a peri-necrotic area in which, and for a certain time interval, the neurons remain structurally intact but functionally inactive. A major finding was that by increasing regional CBF the authors could reverse the electrical failure. Thus, a key issue in the definition of penumbra is the reversibility of the functional failure. Such a key feature is difficult to evaluate in animal models. Since the original definition, the concept of penumbra has evolved to include potentially measurable characteristics, including electrophysiological, biochemical or molecular alterations [17]. For instance, the expression of Hsp70 is being considered a potential marker of the penumbra, in animal models. The expression of Hsp70 in neurons outside areas of infarction is presumed to protect these cells from further protein denaturation, and most cells that express both Hsp70 mRNA and Hsp70 protein appear to survive. Histochemistry for Hsp70 is therefore being considered a reliable tool for identifying in laboratory animals the penumbra area. Other approaches have been used to identify the penumbra, such as protein synthesis, blood flow or metabolic changes defined by a variety of imaging methods [18]. Evaluating differences between regions of abnormal tissue perfusion and diffusion regions on MRI [19] is probably the most common approach in clinical setting. This approach, however, presents flaws and does not directly address the penumbra definition. Most of these approaches are results of conceptualizations aimed to validate an operational definition of penumbra, such to be able to visualize the phenomenon and determine the size and time, in the contest of clinical practice, or at least in the setting of trials.

Traditionally the penumbra is depicted as an area circumscribing the necrotic core. Authors have recently stressed the limit of such a model by emphasizing the heterogeneity of the penumbra itself. In animal models of ischemia there are small islands of the infarcted brain (mini-cores) surrounded by neurons and glial cells that express Hsp70 (mini-penumbra) [17]. The 'most-stressed' cells at the margins of these islands are sometimes neurons and sometimes microglia. We do not know whether such heterogeneity occurs also in humans following stroke, but it is a substantial hypothesis that in vivo neuroimaging approaches underestimate such heterogeneity, and fail in visualizing small islands of recoverable brain tissue within the most affected brain areas.

A number of local and systemic variables affect the outcome of brain cells within the penumbra area. The most relevant variables, as mentioned, are the entity of the local residual CBF and the time interval of the blood flow reduction. There is, therefore, interaction of severity and duration of ischemia in the development of irreversible cell damage. In experimental animals, the penumbra occurs when local CBF is reduced to 20-40% of control (contralateral) values, and the area might be as large as one half of the entire early ischemic lesion [20]. Infarction, in humans, usually corresponds to local CBF values below 12 mL/100g/min and the irreversible damage is thought to occur in a few minutes if the flow is near zero or in 30-60 min if it is close to 12. Penumbra occurs in areas where local CBF decreases to 12-22 mL/100g/min [21].

This is, however, quite a gross approximation as other variables, in addition to intensity and duration, affect the susceptibility of the tissue to the ischemic damage. Such variables include temperature, systemic inflammation, aging or glucose serum levels.

Limits to the Models

Most of the animal models have been carried out in young, healthy animals. There are relatively few reports that emphasize the potential role of variables not directly linked to the obstacle to blood circulation. Considerable interest has been recently devoted to post-ischemic inflammation. Abnormal conditions or diseases, systemic or apparently isolated to other organs, may affect the brain inflammatory response. As a consequence a number of variables not directly associated with the brain ischemia might boost the maturation process or increase the brain tissue liability to the ischemic insult. It is important to appreciate that inflammation starts in the vessel triggered by hypoxia, shear stress and ROS production. Both innate and adaptive immunity is then involved and leads to brain tissue infiltration of inflammatory cells. These inflammatory cells damage the brain by generating cytotoxic mediators and promote programmed cell death. Inflammation embraces a number of different mechanisms, within a complex scenario. For instance, microglia can proliferate and migrate. Activated microglia can assume a primarily cytotoxic phenotype called M1, or an antiinflammatory, protective phenotype called M2. Likely microglia fluctuate in these activation phenotypes during the evolving ischemic process.

Chronic inflammation from atherosclerosis, autoimmune disease, and physiological stress may cause production of proinflammatory cytokines, which diffuse into the brain via the circumventricular organs and activate the resident resting microglia. Resident, immune-competent cells in the brain tissue are likely primed by systemic infection to promote the brain tissue damage following an ischemic insult. Peripheral cytokines, in contact with the endothelial cells that make up the BBB, cause release of various immune molecules into the parenchyma, including NO, prostaglandin E2, IL-1 and IL-6.

Aging itself might prime the microglia. A strong support to the influence of systemic variables on the development of focal ischemic lesions comes from experimental studies carried out by using transplant of mesenchymal stromal cells (MSCs). A large body of evidence indicates that MSCs may aid in reducing the long-term impact of stroke, via multiple mechanisms that include induction of angiogenesis, promotion of neurogenesis, prevention of apoptosis, thus driving plasticity and neurovascular remodeling [22]. However, recent data, in animal models, show that only a very small number of transplanted MSCs

localize to the area of the ischemic lesion. A key feature of MSCs seems to rely on the remote effect that these cells can have. The hypothesis of a remote effect has been strengthened by recent evidence that stem cells release extracellular vesicles. MSCs do in fact release large amounts of exosomes, endocytic small-membrane (30-100 nm) vesicles. These vesicles elicit biological activity similar to the stem cells themselves [23, 24]. Environmental challenges, such as activation or stress conditions, influence the composition, biogenesis, and secretion of exosomes, which likely represent a means by which distant organs or conditions may affect the brain tissue altering its susceptibility to insults.

Animal models currently used are limited in modeling systemic variables that might increase the susceptibility to ischemia. There are, however, a few relevant exceptions. Spontaneously Hypertensive/Stroke Prone Rats develop diffuse brain pathologic changes that mimic subcortical vascular disease [25, 26]. Transgenic mice expressing mutated NOTCH3 protein present dysfunction of the neurovascular units lower threshold for cortical spreading depression, NOTCH3 extracellular domain and osmiophilic deposits, and white-matter lesions resembling CADASIL.

All together, the data gathered in the last 2 or 3 decades, confirm that the residual blood flow associated with occlusion of a vessel is the main but not unique variable causing the brain damage. Furthermore the structural outcome is not the unique variable that affects the prognosis. Together with improvement in methodology for focal or global cerebral blood flow reduction, experimental set up should include modeling of local or systemic variables, which likely affect susceptibility to ischemia, maturation of the post-ischemic damage and restoration and repair.

Chapter 27

THE ADDED VALUE OF NEUROSONOLOGY: A TAX-FREE GENIUS IN THE PROBE

A. Chiti¹ and M. Del Sette²

²Neurology Unit, E.O. Galliera, Genoa, Italy

ABSTRACT

Neurosonology is essential for stroke neurologists, as it can play a key-role in the diagnostic and therapeutic work-up of patients. In this chapter, two challenging issue will be discussed: carotid stenosis (in particular, grading and plaque characterization) and hyperacute revascularization (in particular, intracranial occlusion identification and sonothrombolysis), underlining strengths and limitations of ultrasound in such relevant clinical settings.

Keywords: neurosonology, carotid stenosis, stroke, sonothrombolysis

INTRODUCTION

Neurosonology represents a very informative and relatively unexpensive diagnostic and therapeutic tool, which can be easily implemented at patient's bedside. Its excellent safety, in addition to great spatial and real-time resolution, allows frequently repeatable examinations and monitoring. Operator-dependency, which is related to any type of human activity, is considered one of its main limitations, but it has the potential to be widely reduced by training courses (organized by dedicated scientific societies) and continuous "hands-on" practice. In the multi-disciplinary management of patients with ischemic stroke, neurological clinical skills are essential to "ask" neurosonology proper relevant questions, whose "answers" are expected to integrate and guide diagnostic and therapeutic work-up. A systematic presentation of such complex "dialogue" is beyond the aim of this chapter (to this purpose, see references [1, 2]); here, we focus on emerging pearls (and pitfalls) of neurosonology in two challenging

fields of applications: carotid stenosis and hyperacute revascularization. Of note, it would be better for neurologist and neurosonologist to coexist in the same professionist.

CAROTID STENOSIS: FROM DEGREE QUANTIFICATION TO PLAQUE CHARACTERIZATION

About one third of all ischemic stroke is due to large vessel atherosclerosis, in particular carotid stenosis, with high risk of early recurrence [3]. This is also true for cases with transient ischemic attack due to such disease [4]. Early carotid endarterectomy (CEA) proved greatly effective in reducing stroke risk in selected patients with symptomatic carotid stenosis ranging from 50 to 99% [5-7]. On these premises, after answering the questions “Has the patient suffered an ischemic stroke or transient ischemic attack? In which cerebrovascular district?”, neurologist should search for the etiopathogenesis of the event to “tailor” proper secondary prevention. As for potential selection for early CEA, neurologist should ask neurosonologist: “Has the patient a carotid stenosis? What is the degree of stenosis? May I trust you or should I ask radiologist another imaging technique such as CT/MR angiography or digital subtractive angiography?” These questions have been recently addressed by von Reutern *et al.*, who summarized the internationally available experience with ultrasonic grading of carotid stenosis [8].

Assessment of Plaque Morphology and Haemodynamic Effect

Pathogenesis of stroke due to carotid plaque relies on both hemodynamic effects (attributable to area reduction, not diameter reduction) and a complicated structure/surface eventually leading to emboli or occlusion. Diameter reduction alone is insufficient to evaluate the degree of stenosis, especially irregular ones, so that Doppler ultrasound and X-ray (or MR, CT) angiography each measure different biological variables and total agreement is impossible. Here, we focus on degree evaluation; advanced plaque characterization by ultrasound (e.g., plaque composition, plaque vascularization, thickness of the cap, plaque ulceration, and plaque motion) will be discussed in a further section.

Ultrasound B-mode accurately detects arterial wall thickness and minor plaques, providing multi-plane images of the wall itself and not only from the blood column. In case of severe stenosis, cross-sectional B-mode images are more difficult to generate because of shadowing and other artifacts; the same is true for color flow. Therefore, the more severe a stenosis, the more hemodynamic criteria are prevailing. The relationship between area and diameter reduction depends on the type of stenosis: in eccentric plaques diameter and area reduction are similar, while in concentric ones percentage area reduction is higher than the measured diameter reduction [9]; kidney-shaped or irregular plaques deserve a more complex evaluation. Despite these limitations, diameter reduction as shown by X-ray angiography (with “distal method” or “local method”) is considered to be the gold standard for decision-making because it was used respectively in NASCET and ECST trials. The “distal method” (NASCET) calculates the ratio of the minimal residual diameter of the stenosed segment to the diameter of a distal, clearly non-diseased segment of the internal carotid artery. It

corresponds better to the hemodynamic effect and it is preferred by radiologists and in existing guidelines for clinical decisions; however, this method has a relevant limitation in cases of very severe stenosis, where poststenotic flow volume diminishes and in consequence the diameter of the distal segment “collapses”, leading to a lower calculated degree of stenosis [10]. The “local method” (ECST) calculates the ratio of the minimal residual diameter of the stenosed segment to the presumed former diameter of the same segment; it better-illustrates plaque burdening. Both NASCET and ECST types of measurement are feasible with B-mode imaging if it is possible to visualize the residual lumen of the stenosis and the lumen of the poststenotic segment; Color flow imaging alone is less reliable for taking diameter or area measurements because of the influence of the gain setting.

Arterial narrowing leads to locally increased velocities; a hemodynamic effect is reached when pressure and flow volume are diminished in the poststenotic segment. When this effect is present, there is a raised risk of ischemia associated to a complicated plaque structure prone to embolism and/or insufficient blood supply. Flow velocity (in particular, peak systolic velocity, PSV) measured by means of Doppler sonography correlates with the narrowing measured in area reduction, as shown by the “Spencer’s curve.” [11]. However, when compared to X-ray angiography, degree of stenosis determined through PSV show considerable scattering of results [12-16], so that Duplex sonography has not been accepted as the sole methodology for definitive diagnosis by the American Heart Association [17]. Such disagreement can be explained by several reasons:

- First, there is the morphology of the stenosis as discussed above (area versus diameter; irregularities ill-represented).
- Second, there is ambiguity of the “Spencer’s curve,” with the possibility of the same velocity in a moderate stenosis and a nearly occluded artery; mimics of near occlusion include occlusion, intracranial disease, severe stenosis and even no stenosis [18].
- Third, measuring the angle of insonation needed for converting recorded Doppler frequencies into velocities may be subjected to errors due to disturbed flow (with stream lines differing from the vessel course) at the site of stenosis [19].
- Fourth, there is the influence of collateral flow. In a hemodynamically significant stenosis, the higher the capacity of intracranial collateral network (via the circle of Willis and, less effectively, via the ophthalmic artery, which differ from patient to patient), the less the poststenotic pressure decrease and, consequently, the intrastenotic velocity [20]. The same holds true for the PSV contralateral to an internal carotid artery occlusion [21].
- Fifth, there is the technical problems of spectrum analysis. At the site of stenosis, the Doppler spectrum is generated by both low-frequency components (due to vortices and flow separation) and high-frequency ones (due to jet), but the relative weight of the latter can be so low that it’s difficult to detect without special high-pass filtering or setting of the gain, leading to underestimation of the PSV [22].

Considering all these limitations, PSV as a single simplified diagnostic parameter appears insufficient. However, further ultrasound criteria (such as post stenotic PSV, collateral flow, end-diastolic flow velocity in the stenosis, “carotid ratio” – that is ratio of internal to common carotid PSV) allow to decide whether a measured PSV represents a less or more severe

stenosis within the scatter range. In particular, according to a multiparametric approach, carotid stenosis could be classified as follows:

- Low-degree stenosis 0% to 40% (NASCET). Velocity measurement rules out a more severe stenosis (e.g., PSV < 125 cm/second). B-mode imaging (in the longitudinal and cross-sectional planes) allows plaque detection and measures of reduction of diameter in percent, the thickness and length of the plaque as well as the residual lumen. Collateral flow is not present and carotid ratio is <2.
- Moderate stenosis 50% to 70% (NASCET). Local increase of velocity (e.g., 125 < PSV < 230 cm/second) and B-mode imaging can be combined for grading; collateral flow is not present, carotid ratio is >2 and end-diastolic flow velocity in the stenosis is <100 cm/second.
- Hemodynamically relevant stenosis >70% (NASCET) and occlusion. This is the domain of combined hemodynamic criteria: PSV > 230 cm/second; carotid ratio is >4 and end-diastolic flow velocity in the stenosis is >100 cm/second (except for 90% stenosis). Collateral flow may be demonstrated by examining the ophthalmic artery branches (omolateral external-internal artery supply), the anterior cerebral artery (proving cross-flow from contralateral internal carotid artery) or the P1 segment of the posterior cerebral artery (indicating collateral flow through the posterior communicating artery). Poststenotic flow velocity in the segment distal to the disturbed flow field is another useful criterion: if it is <50 cm/second the stenosis is about 80%, if it is <30 cm/second stenosis is about 90%. Color flow imaging is important as a guide for velocity measurement and, in addition to B-mode, is essential for differentiating occlusion from stenosis.

With a refined multiparametric ultrasound approach, used by skilled and certified operators, neurosonology for degree quantification of carotid stenosis warrants further re-evaluation in the guidelines regarding the management of such patients.

Assessment of Plaque Vulnerability

Moreover, ultrasound techniques have the potential to evaluate plaque vulnerability, allowing detection of cases at high risk of cerebrovascular ischemic events, which deserve aggressive diagnostic and therapeutic work-up. At present, only cases with recently symptomatic, moderate-to-severe carotid stenosis have a clear indication to early carotid endarterectomy; however, such indication could be extended to patient with “cryptogenic” TIA/stroke in the anterior circulation and moderate carotid stenosis due to a vulnerable plaque [23]. Furthermore, indications for CEA (with its related cost-effectiveness) in asymptomatic patients is currently under debate [24], mainly because medical therapy has greatly improved since ACAS trial, which randomized patients to CEA vs best medical therapy (supporting CEA) about 20 years ago [25]; in this context, neurosonology may help selecting cases with vulnerable plaque, which could be “truly good” candidates for CEA.

To better elucidate such issue, a systematic review and meta-analysis of ultrasound characteristics of symptomatic carotid plaques has been recently published by Brinjikji et al. [26]. First, authors defined ultrasound features of interest as follows:

- Heterogeneous echotexture: mixture of hypoechoic, isoechoic and hyperechoic lesions and/or heterogeneity in Gray-Scale-Median scores with mixture of hyperechoic, hypoechoic and isoechoic lesions
- Intraplaque motion: presence of mobile components within the plaque or on the plaque surface
- Irregular surface: irregular plaque surface with recesses less than 2 mm in depth
- Plaque echolucency: Type I, uniformly anechoic or Type II predominantly hypoechoic or anechoic with less than 50% echogenic areas. Or Gray-Scale-Median score below 30.
- Plaque neovascularity: plaque enhancement with contrast ultrasound imaging or areas of intraplaque Doppler or power Doppler signal consistent with neovascularity
- Ulceration: plaque surface crater measuring 2 mm or more or concavity with an echogenic line at the plaque base
- Complex plaque: any one of the above imaging features

After that, Authors screened and identified over one thousands published manuscripts (using MEDLINE and EMBASE) and included 23 papers with usable information in the final analysis. Ultrasound plaque characteristics with a higher prevalence in individuals with symptomatic compared to asymptomatic carotid artery stenosis included plaque neovascularity (OR = 19.68, 95% CI = 3.14 – 123.16), complex plaque (OR = 5.12, 95% CI = 3.42–7.67), plaque ulceration (OR = 3.58, 95% CI = 1.66 – 7.71), plaque echolucency (OR = 3.99, 95% CI = 3.06 – 5.19) and intraplaque motion (OR = 1.57, 95% CI = 1.02 – 2.41). Variables not associated with symptom status included heterogenous echotexture (OR = 2.68, 95% CI = 0.56 – 12.80) and surface irregularity without ulceration (OR = 2.38, 95% CI = 0.70 – 8.11).

In addition to direct plaque evaluation at the cervical level, ultrasounds can depict plaque instability through transcranial Doppler monitoring of microembolic signals (MESs) on ipsilateral middle cerebral artery. MESs detected in patients with carotid artery disease are due to unstable plaque and rapidly diminish following CEA [27]. In a systematic review of the literature, Ritter et al. found that 43% of patients with symptomatic carotid stenosis had MESs on TCD compared with just 10% of asymptomatic patients [28]. Furthermore, presence of just 1 MES was associated with 7.5 times higher odds of future symptomatic events in symptomatic patients and 13.4 times higher odds of embolic event in asymptomatic patients. Conversely, absence of MESs is associated with a very low risk of future symptoms in patients with asymptomatic carotid plaques. [29, 30].

In conclusion, ultrasound can usefully integrate other imaging modalities (X-ray angiography, CTA, MRA, PET) to evaluate degree of stenosis and plaque vulnerability [31].

HYPERACUTE REVASCULARIZATION: FROM DETECTION OF OCCLUSION TO SONOTHROMBOLYSIS

Until recently, intravenous tissue plasminogen activator (tPA) administered within 4.5 hours after symptom onset has been the only reperfusion therapy with proven efficacy in patients with acute ischemic stroke [32]. Pathogenesis of stroke is mainly due to arterial

occlusion and the aim of tPA is to achieve early vessel recanalization, saving ischemic penumbra and avoiding stroke-related long-term disability [33]; essential selection criteria for intravenous thrombolysis don't include vessel imaging, but determination of site of occlusion and monitoring of recanalization have allowed relevant advancements in stroke therapy.

For instance, intravenous tPA appears to be much less effective at opening proximal occlusions of the major intracranial arteries (which account for more than one third of cases of acute anterior-circulation stroke) [34], leading to poor prognosis [35]. Recent trials [36-40] have shown that, in selected patients with stroke due to proximal intracranial arterial occlusion in the anterior circulation, endovascular treatment (on top of standard therapy) significantly improves patients' outcome. On these premises, neuroimaging and endovascular therapy have to be considered key-elements in the current management of patients with hyperacute stroke; here, we focus on the diagnostic and therapeutic role of ultrasounds, which may usefully integrate such armamentarium.

Diagnosis and Monitoring: The TIBI Score

Grading and characterization of extracranial carotid stenosis have been discussed in the previous section. Ultrasound evaluation of hypoplasia, stenosis and occlusion in the vertebrobasilar system is feasible too [41]. In the hyperacute setting, assessment of intracranial arteries is crucial; Demchuk et al. developed a Thrombolysis in Brain Ischemia (TIBI) classification by using transcranial Doppler (TCD) to detect and monitor intracranial vessel residual flow signals in middle cerebral artery and basilar artery [42]:

- Grade 0: absent. Absent flow signals are defined by the lack of regular pulsatile flow signals despite varying degrees of background noise.
- Grade 1: minimal. Systolic spikes of variable velocity and duration; absent diastolic flow during all cardiac cycles based on a visual interpretation of periods of no flow during end diastole; reverberating flow is a type of minimal flow.
- Grade 2: blunted. Flattened systolic flow acceleration of variable duration compared to control; positive end diastolic velocity and pulsatility index <1.2.
- Grade 3: dampened. Normal systolic flow acceleration; positive end diastolic velocity; decreased mean flow velocities (MFV) by >30% compared to control.
- Grade 4: stenotic. MFV of >80 cm/s and velocity difference of >30% compared to control side; if both affected and comparison sides have MFV <80 cm/s, due to low end-diastolic velocities, MFV >30% compared to the control side and signs of turbulence. Of note, criteria for intracranial stenosis (>50%) assessment through transcranial color-coded duplex (TCCD) sonography had been published by Baumgartner et al. in 1999 [43].
- Grade 5: normal. <30% mean velocity difference compared to control; similar waveform shapes compared to control.

In the same manuscript, Demchuk et al. reported about 109 patients undergoing intravenous thrombolysis, finding that pre-tPA National Institute of Health Stroke Scale (NIHSS) score were higher in patients with TIBI grade 0 than TIBI grade 4 or 5 flow [42]. Moreover, TIBI flow improvement to grade 4 or 5 occurred in 35% of patients with an initial

grade of 0 or 1 and in 52% with initial grade 2 or 3; the 24-hour NIHSS scores were higher in follow-up in patients with TIBI grade 0 or 1 than those with TIBI grade 4 or 5 flow. TIBI flow recovery correlated with NIHSS score improvement; on the other hand, lack of flow recovery predicted clinical worsening or no improvement. In-hospital mortality was 71% for patients with posterior circulation occlusions; it was 22% for patients with pre-tPA TIBI 0 or 1 compared with 5% for those with pre-tPA TIBI 2 or 3 anterior circulation occlusions [42].

Such findings were confirmed by Saqqur et al., who reported that clinical response to thrombolysis was influenced by the site of occlusion: patients with no detectable residual flow signals (as well as those with terminal internal carotid artery occlusions) resulted least likely to respond early or long term [44].

FROM DIAGNOSIS TO TREATMENT: SONOTHROMBOLYSIS

Delivery of tPA to and through the thrombus is likely dependent on minuscule residual red blood cell flow around the thrombus and plasma flow through the thrombus [45]. Mechanical agitation can expose shallow layers of thrombi to circulating tPA and facilitate streaming of plasma through the thrombus, thus bringing more tPA to binding sites. Ultrasound is a pressure wave that can travel through tissues and deliver this mechanical momentum to stagnant flow areas and clot interfaces. Several experiments have confirmed the ability of ultrasound to enhance fibrinolysis through disaggregation of non-cross-linked fibrin strands, further thinning them, and promoting plasma flow and lytic drug delivery to the clot [46-48]. Kilohertz frequencies were thought to induce more mechanical stretching, whereas megahertz ultrasound promotes fibrinolysis more through enzymatic mechanisms [49, 50]. In 2000 Alexandrov et al. serendipitously discovered as part of the clinical routine that stroke patients with intracranial arterial occlusion treated with systemic tPA and monitored with 2-MHz transcranial Doppler (TCD) could recanalize early during treatment and experienced dramatic clinical recovery. This observation was subsequently confirmed in a randomized controlled trial called CLOTBUST (Combined Lysis of Thrombus in Brain ischemia using transcranial Ultrasound and Systemic tPA) [51]: among 126 enrolled patients with stroke due to middle cerebral artery occlusion (63 patients in each group), 83% achieved any recanalization (46% complete, 27% partial) with tPA and TCD versus 50% (17% complete, 33% partial) with tPA alone within 2 hours of treatment ($P < 0.001$). Sustained complete recanalization at 2 hours was 38% versus 13%, respectively ($P = 0.03$).

In the last 15 years, several groups have tested ultrasound with tPA (“sonothrombolysis”) or ultrasound without tPA (“sonolysis”, in patients with contraindications to tPA) according to different protocols, varying in duration (from one to two hours), frequency (TCD with 2.0 MHz; TCCD with 1.8 MHz; low frequency, non-diagnostic ultrasound of 300 KHz) and use of microbubbles (which have the potential to enhance the mechanical action of ultrasound). Of note, TRUMBI trial using low frequency ultrasound (300 kHz) was prematurely interrupted for safety reasons because the authors observed an excess of intracranial haemorrhages in the treated group in comparison with control patients [52]. As for site of occlusion, middle cerebral artery (whose monitoring is feasible through simple probe-supporting helmets, too) was the most studied vessel, while very small data exist on patients with internal carotid artery terminus or basilar artery occlusion, whose natural history lead to

a very bad prognosis [53, 54]. The results of principal published studies have been reviewed in the last few years by Tsivgoulis et al., Ricci et al., Saqqur et al. 2014 [55-57]. Among these, the manuscript by Ricci et al. included only randomized controlled trials [58-62], with a total of 233 patients. As for main results, Authors reported that:

- For the primary outcome (death or dependency at three months), five studies with a total number of 206 patients were available (four defined independence as a modified Rankin score of 0 to 2 and one used 0 to 1). Patients treated with sonothrombolysis were less likely to be dead or disabled at three months (odds ratio (OR) 0.50, 95% confidence interval (CI) 0.27 to 0.91).
- For the secondary outcomes, failure to recanalise was lower in the sonothrombolysis group (230 patients) (OR 0.28, 95% CI 0.16 to 0.50), no significant difference was found in mortality (206 patients) and in cerebral haemorrhage (233 patients).

In conclusion, sonothrombolysis appeared to reduce death or dependency at three months (although CIs were quite wide), and increased recanalisation without clear hazard; however, a larger clinical trial was warranted. To this purpose, an Italian randomized multicentric pilot study called “ULTRAS” (Ultrasound Thrombolysis in Acute ischemic Stroke) is on-going.

Moreover, potential future development of sonothrombolysis include engineering of microbubbles (such as fibrin-targeted microbubbles, tPA loaded liposomes and immune-particles) [63-65], intra-arterial administration of ultrasound (through EKOS catheter [66]) or microbubbles [67], hands-free transcranial Doppler device [68]. Taken together, current evidence and future perspectives suggest that ultrasound may usefully integrate therapy of patients with hyperacute ischemic stroke.

Chapter 28

INTRAVENOUS THROMBOLYSIS: PRESENT EVIDENCES AND FUTURE PERSPECTIVES

Danilo Toni* and Alessio Pieroni

Emergency Department Stroke Unit, Hospital Policlinico Umberto I,
Department of Neurology and Psychiatry, 'Sapienza' University, Rome, Italy

ABSTRACT

Intravenous thrombolysis is a widely established therapy for the hyperacute management of ischemic stroke and has been increasingly recognised over the years as the crucial treatment to reduce stroke disability and mortality. The progressive diffusion of Stroke Units, the raising awareness about cerebrovascular disease and the revision of inclusion and exclusion criteria, led to a larger amount of patient to benefit from thrombolytic therapy. Several trials are ongoing to enhance the efficacy and safety of thrombolytic agents and to grant to a larger amount of patient to be efficaciously treated. This chapter describes the studies that led to the approval of use of the recombinant tissue plasminogen activator for the treatment of acute stroke and past and current trials with newer thrombolytic agents and advanced diagnostics and therapeutic techniques.

Keywords: intravenous thrombolysis, stroke, stroke unit, alteplase, tenecteplase, desmoteplase

INTRODUCTION

Since its introduction in late '90s, intravenous thrombolysis (IV TL) with Alteplase played a crucial role in the therapy for acute ischemic stroke in patient admitted to Stroke Units and was increasingly established all around the world. Several indications and contraindications to therapy changed during the years, especially with a progressive enlargement of the therapeutic window that, together with a widespread diffusion of Stroke

* Corresponding Author's Email: danilo.toni@uniroma1.it.

Units, led to a larger amount of patients to be eligible for the treatment. Results from several randomized controlled trials (RCTs) led to the approval of use of the recombinant tissue plasminogen activator (rt-PA, *alteplase*) within 4,5 hours from symptoms onset on November 2010 in Europe by the *European Medicines Agency* (EMA).

INTRAVENOUS THROMBOLYSIS

Clot dissolving drugs produce their effect by restoring the blood flow through the hypoperfused tissues in the so-called ischemic penumbra, where a potentially salvageable area suffer from the reduction of blood supply. However, since the brain cells rapidly die from the time the ischemic injury occurs, reperfusion therapy may be more efficacious the earlier they are administered.

The first attempts to treat stroke patients with clot dissolving drugs were carried out in the 90s with *Streptokinase*, a polypeptide derived from the β -haemolytic *Streptococcus*, and *Urokinase*, a human derived enzyme, but they showed an excessive increase in symptomatic intracranial haemorrhage (sICH). Newer generation thrombolytic agents with shorter half-life and more fibrin-specificity (*alteplase*, *pro-urokinase*, *reteplase*, *tenecteplase*, *desmoteplase*) were later evaluated but only alteplase has been licensed for use within 4.5 hours of stroke in the US, Canada and Europe.

Result of several RCTs, the *National Institute of Neurological Disorders and Stroke* (NINDS) *study group trial* [1], the *European Cooperative Acute Stroke study I* (ECASS) [2] and *II* (ECASS II) [3], the *Alteplase ThromboLysis for Acute Noninterventional Therapy in Ischaemic Stroke* (ATLANTIS) *study* [4], and their pooled analysis [5] showed that IV TL with rt-PA, despite a greater incidence of hemorrhagic transformation, is a highly effective treatment in selected patients with acute ischemic stroke.

Basing on this data, in September 2002, the EMA released a conditional approval for use of rt-PA at a dose of 0.9 mg per kilogram body weight with a maximum of 90 mg, infused intravenously over 60 minutes, with 10% of the total dose administered as an initial bolus. As requested by the EMA, stroke patients treated with rt-PA were recruited in the post-marketing observational *Safety Implementation of Thrombolysis in Stroke-Monitoring Study* (SITS-MOST) with the aim to verify the safety and efficacy profile of IV TL in a “real world” routine clinical practice.

Begun on December 2002 and completed on April 2006, the SITS-MOST study treated 6483 patients in 285 centres among 14 European countries. Symptomatic hemorrhagic infarction (sICH), defined as a clinical worsening of at least 1 point on the NIHSS scale in the presence of any type of intracerebral bleeding, occurred in 7.3% (95% CI 6,7-7,9) of patients, compared with 8,6% (95% CI 6,3-11,6) of the previous RCTs; the mortality rate at 3 months amount to a total of 11,3% (95% CI 10,5-12,1) against 17.3% (95% CI 14,1-21,1) in RCTs. The efficacy of treatment, evaluated on patients who reach a modified Rankin scale (mRS) score of 0-2 at 3 months, was achieved by 54.8% (95% CI 53,5-56,0) compared with 49.0% (95% CI 44,4-53,6) in RCTs [6]. Therefore, SITS-MOST results largely confirmed those of RCTs and a final approval of rt-PA within the 3 hours window was released by EMA in 2006.

A review of SITS-MOST showed a substantial undertreatment compared to the numbers of potentially eligible patients, mainly because acute stroke patients arrived at the treatment

hospitals beyond the therapeutic window. Same figures were reported in the US [7] where the potential number of treated patients would be increased tenfold with strategies to reduce the door to needle time [8]. Regarding to this, it is noteworthy that by the end of the SITS-MOST study, the recruitment of new centres, clearly not experienced in IV TL, increased by 50% without any substantial modifications in treatment safety and efficacy. Hence, the importance of efforts to implement the Stroke Units, together with strategies adopted to extend the therapeutic window. The meta-analysis of the individual data of ATLANTIS, ECASS I-II, and NINDS trials showed an efficacy of IV TL until 4,5 hours from the symptoms onset, despite a time related reduction of the effect [5]. Hence, as an adjunctive request by the EMA, a new randomized placebo-controlled trial, the *European Cooperative Acute Stroke study III* (ECASS III), was done to verify the efficacy and safety of IV TL versus placebo in the 3 to 4,5 hours therapeutic window. Patients treated with alteplase reached a more favourable outcome than those in placebo group (52,4% vs. 45,2%, adjusted OR of favourable outcome - mRS 0/1: 1,42, 95% CI 1,02-1,98) even with a higher incidence of sICH (7,9% vs. 3,5% - OR 2,38, 95% CI 1,25-4,52). However, mortality did not differ significantly between the two groups (7,7% vs. 8,4% - OR 0,90 95% CI 0,54-1,49) [9]. At the same time, based on “real life” data from the SITS International Stroke Registry (SITS-ISTR), results from the comparison of 664 patients receiving IV TL between 3 and 4,5 hours and those treated within the 3 hours window, confirmed the same efficacy and safety of rt-PA between the two groups for any outcome measures. A functional independence was achieved by 58,0% and 56,3% of patients respectively (aOR 0,93 95% CI 0,84-1,03), with an incidence of sICH of 8,0% vs. 7,3% (aOR 1,13 95% CI 0,97-1,32) and mortality rate of 12,7% vs. 12,2% (aOR 1,15 95% CI 1,00-1,33). Such encouraging results, led to the approval of the extension to 4,5 hours of the therapeutic window for alteplase by EMA in 2010.

Over the same time, more than 3000 ischemic stroke patients were randomized to rt-PA or control in the *International Stroke Trial 3* (IST 3) within the 6 hours windows, regardless of age or severity of neurological deficits. Basing on the uncertainty principle, a large amount of patients not fulfilling EMA license criteria for the use of rt-PA (95%) was randomized. At 6 months, a functional independence was achieved by 37% of treated patients and 35% of controls (OR 1,13 95% CI 0,95-1,35), ICH occurred in 7% vs. 1% respectively, while mortality was similar in both groups (27%). Moreover, the treatment within 3 hours showed its greater efficacy in over-80 patients and in those with more severe stroke at onset [10].

Results from a further 2014 pooled analysis of individual data of 6756 patients from all the published RCTs with alteplase, showed that IV TL within 4,5 hours was associated with an increase of the odds of a good outcome at 3 to 6 months, irrespective of stroke severity at onset. Moreover, a clear correlation between the onset-to-treatment (OTT) interval and efficacy of rt-PA treatment was found (OTT $\leq$ 3 hours: OR 1,75 95% CI 1,35-2,27; OTT 3-4,5 hours: OR 1,26 95% CI 1,05-1,51; OTT >4,5 hours: OR 1,15 95% CI 0,95-1,40), highlighting the overwhelming importance of an early treatment in stroke patients. The analysis also showed an increase in the odds of sICH in rt-PA treatment group (PH2 definition: 6,8% vs. 1,3% OR 5,55 95% CI 4,01-7,70; 7 day fatal ICH 2,7% vs. 0,4% OR 7,14 95% CI 3,98-12,79), and its significant correlation with stroke severity, while similar mortality rates was found between the two groups (HR 1,11 95% CI 0,99-1,25) [11].

A large international double-blind trial is ongoing to randomize patients to rt-PA treatment between 4.5 and 9 hours after symptom onset or with unknown time-window: the *European Cooperative Acute Stroke Study-IV* (ECASS IV). Patients are selected via Magnetic

Resonance (MR) evidence of a penumbral mismatch defined as a perfusion volume (perfusion weighted image, PWI) to infarct core (diffusion weighted image, DWI) ratio of ≥ 1.2 , and a minimum perfusion lesion volume of 20 ml and followed up at 3 months [12].

NEWER THROMBOLYTIC AGENTS: DESMOTEPLEASE, TENECTEPLASE

The thrombolytic agent from vampire bat saliva, *desmoteplase*, was tested in several trials of acute ischemic stroke with a longer therapeutic window, due to a lower neurotoxicity and consequently lower incidence of hemorrhagic complications, compared with rt-PA. The first trial, the Desmoteplase in Acute Ischemic Stroke Study (DIAS), treated 104 patients within 3 to 9 hours after stroke onset based on mismatch criteria on PWI/DWI MR imaging [13]. The study demonstrated that IV desmoteplase administration was associated with a better clinical outcome compared with placebo, with low sICH rate. Remarkably, patients treated within 6-9 hours had same chances for a good clinical outcome as patients treated in the 3 to 6 hours time window. The subsequent *Dose Escalation of Desmoteplase in Acute Stroke* (DEDAS) trial confirmed that treatment with IV desmoteplase 3 to 9 hours after ischemic stroke onset appeared safe and improved clinical outcome in patients fulfilling MR mismatch criteria [14].

Unfortunately, the following two studies did not confirm the good results of previous ones. The DIAS II, investigating the efficacy of 2 doses of desmoteplase in stroke patients with a distinct ischemic penumbra of at least 20%, found no significant differences between the groups in clinical response rates, while mortality rate was higher in the highest-dose group. The DIAS-III/IV recruited patients with a high-grade stenosis or occlusion in proximal cerebral arteries supplying the infarct area, treated within 3-9 hours after the symptoms onset. The trial was stopped prematurely due to futility analysis.

Among the newer thrombolytic drug, *tenecteplase* (TNK), a modified recombinant tissue plasminogen activator molecule, showed promising as a potentially safer alternative to alteplase. IV TL with rt-PA was compared with different doses of TNK in two, phase 3, RCTs [15, 16], subsequently included in a Cochrane review [17] where no significant statistical differences emerged from the 2 studies (187 pts) about the death and dependency outcome measure. Moreover, the trial of Haley and colleagues [16] included a higher dose TNK group (0.4 mg/kg) was discontinued because of safety concerns about incidence of sICH at that dose, whereas imaging selection criteria in the trial of Parsons and colleagues [15] resulted in exclusion of a large amount of patients who were otherwise eligible for rt-PA. Hence, the *Alteplase-Tenecteplase Trial Evaluation for Stroke Thrombolysis* (ATTEST) [18], compared the outcome of IV TL with TNK (0.25 mg/kg maximum 25 mg, 52 pts) versus rt-PA (standard dosage, 52 pts) within 4.5 h of stroke onset, in patients not selected on the basis of advanced neuroimaging. No significant differences were noted in terms of percentage of penumbral tissue salvaged, incidence of sICH, total ICH events or incidence of serious adverse events between the TNK and rt-PA groups.

The previously mentioned 2013 Cochrane review [17] also compared different outcome measures for thrombolytic treatment with rt-PA, urokinase, desmoteplase and TNK at different drug dosages but failed to found a superiority of a drug to another. Result from 7 studies with 730 patients showed no differences for the death and dependency outcome

measure, while non-conclusive evidences that higher doses correlate with higher rate of fatal ICH were found analysing 1274 patients in 10 studies. A RCT is ongoing with the aim to compare the standard rt-PA dosage (0.9 mg/Kg) with a low-dose (0.6 mg/Kg). This part of the *Enhanced Control of Hypertension and Thrombolysis Stroke Study* (ENCHANTED) [19] finished its recruitment on 17 August 2015 with more than 3300 patients randomized.

THROMBOLYSIS IN THE ELDERLY

Among the efforts to implement thrombolytic treatment in acute ischemic stroke, one must consider the enlargement of IV TL to older patients. Due to the progressively increasing burden of common risk factors such as dyslipidemia, hypertension, cardiovascular disease and diabetes during the age, cerebrovascular diseases tend to be more and more common in older population. Unfortunately, patients aged over 80 years old had been poorly represented in first clinical trials due to their highest comorbidity rate and presumed poorer outcome. Older patients have the highest absolute risk of death following a stroke and are more likely to require long-term care than younger ones. A first survey on IV TL in over 80 showed a higher mortality compared to younger patients, with lower rate of favourable outcome, despite the same rate of sICH [20]. Data from the NINDS trial [1] suggested that younger patients benefit from thrombolytic treatment more than older ones when adjusted for stroke severity and the multivariable analysis of outcome predictors in the SITS-MOST study and pooled RCTs found that older age was related to poor outcome [21]. However, further results emerged from the large cohort of over 80 patients in the IST 3 (53% of the total) where the benefit of treatment in this group was, actually, as large as in younger patients [10]. Similar results was found in a large subsequent pooled analysis, with an amount of 1729 of over 80 patients (26% of the total), where age was shown not to change the effect of alteplase on odds of a good outcome nor on incidence of fatal ICH [11].

INFLUENCE OF GENDER

Even if the natural history of stroke showed that women have a worse outcome than men, early works suggested that they could benefit from a better response to thrombolytic treatment with higher recanalization rate and better functional outcome [22, 23]. The analysis of baseline characteristics of women from the SITS-MOST study showed that they were older, had a higher NIHSS score at baseline and were more likely to have a history of arterial hypertension and atrial fibrillation compared to men, whereas the latter were more frequently affected by hyperlipidemia and diabetes mellitus and had a smoke habitus. No differences were found in the 3-month favourable outcome after corrections for confounders, confirming that IV TL may modify the outcome favouring women as compared to the natural course of stroke. Male sex actually resulted independently associated with a higher odds ratio for sICH and mortality [24].

NEURO-IMAGING TECHNIQUES CONTRIBUTION

Advanced neuro-imaging techniques could improve the efficacy and safety of IV TL, extending the therapeutic window and leading to a more accurate selection of patients. Brain computed tomography and MR, with perfusion and angiographic study, and Ultrasound techniques have given interesting results. MR can suggest useful prognostic information about safety and efficacy of IV TL when patients arrive beyond the 3 hours time window or when exhaustive anamnestic information is lacking. This could be of extreme utility for those patients with wake up stroke or for those aphasics and living alone, when the onset of symptoms could not be determined at all. A potentially salvageable brain tissue could be found in more than 80% of stroke patients in the 3 to 6 hour time interval and an eventual recanalization could be strongly influenced by the promptness of treatment [25-27]. The *Diffusion and perfusion imaging Evaluation For Understanding Stroke Evolution* (DEFUSE) study showed that baseline MR findings could identify subgroups that are likely to benefit from IV TL 3 to 6 hours after symptoms onset, based on mismatch profile and extent of DWI area [28]. Moreover, in the *Echoplanar Imaging Thrombolytic Evaluation Trial* (EPITHET) the site of arterial obstruction was found to be a strong predictor of outcome after rt-PA administration in the 3 to 6 hour interval [29]. Based on MRA data, the study showed that internal carotid artery (ICA) obstruction carries a poor prognosis, whereas good outcomes are associated with middle cerebral artery obstruction. A subsequent analysis of both studies suggested that the infarct growth attenuation after rt-PA over placebo was greater in patients with baseline arterial obstruction than those without [30].

Proximal intracranial occlusion has thought to be a target for ultrasound-enhanced thrombolysis. Ultrasound techniques are not only fast and reliable non-invasive methods to assess regional blood flow but, when combined with thrombolytic therapy, they showed to improve recanalization of occluded vessels. A meta-analysis of 6 randomized and 3 nonrandomized clinical studies of several *sonothrombolysis* methods suggested, in 2010, that ultrasound and rt-PA increase the likelihood of recanalization compared to IV TL alone, without a raised risk of sICH [31]. A subsequent Cochrane revision, 2 years later, evaluated 206 patients from 5 studies finding a net benefit of sonothrombolysis in reducing death and disability and in determining an early recanalization [32]. Same figures were found analysing the 191 patients randomized at IV TL alone or at sonothrombolysis plus IV TL. Moreover, a subanalysis of one of the evaluated studies, the CLOTBUST trial, showed a higher efficacy of sonothrombolysis in patients with occlusion of major intracranial vessels [33]. However, due to the small number of patients and trials heterogeneity, recommendations for the use of sonothrombolysis in clinical practice cannot be done. A recent RCT to evaluate the safety and efficacy of transcranial ultrasound, using an operator-independent headframe, as an adjunctive therapy to rt-PA treatment in subjects with acute ischemic stroke (CLOTBUSTER) has been terminated on April 2015 [34].

THROMBOLYSIS IN SPECIAL CONDITIONS

The efficacy of thrombolytic treatment for acute strokes with uncommon aetiology or special situations such as ICA occlusion, cerebral venous and dural sinus thrombosis, cervical artery dissection and pregnancy, has also been considered.

The efficacy and safety of IV TL in patients with acute stroke due to ICA occlusion was studied in the *Systemic Thrombolysis in Patients With Acute Ischemic Stroke and Internal Carotid ARtery Occlusion* (ICARO) study [35]. The comparison of patients with acute ischemic stroke and ICA occlusion treated within 4,5 hours (253 pts) to matched non treated patients (253 pts), showed that thrombolytic therapy increases the chances to reach a favourable outcome, even though it leads to higher death and intracranial bleeding rates. The association with ICA occlusion and adverse outcome was confirmed in a subsequent analysis of consecutive patients treated with IV TL, divided into those with (137 pts) and those without ICA occlusion (1761 pts). Death and death or disability rates at 90 days were found to be higher in ICA occlusion group, even after logistic regression analysis [36].

Ischemic strokes in the posterior circulation account approximately from 11% to 16% of all ischemic strokes and have been suggested to have different etiopathogenetic, clinical and outcome characteristics. Recent unpublished data shown that IV TL in patients with posterior circulation stroke (291 pts, 12%) compared to those with anterior circulation stroke (2163 pts) lead to similar mortality rates and favourable outcome chances. Moreover, vertebrobasilar strokes independently predicted lower risk of sICH after IV TL, but only according to the less severe NINDS definition.

A particular and threatening condition is that of basilar artery occlusion (BAO), presenting high mortality rates. A systematic review in patients with acute BAO, comparing endovenous and endovascular treatment, showed unfavourable results in term of mortality and disability with low rates of good outcome in both treatment groups [37]. Similar findings emerged from the *Basilar Artery International Cooperation Study* (BASICS) where patients with BAO were treated mainly with intra-arterial therapy or IV TL or antithrombotic treatment only: high rates of unfavourable outcome (mRS 4-6: 69%) and mortality (39%) were found, and no unequivocal superiority of one treatment on the others could be established [38-40].

The use of IV TL in patients with cerebral venous and dural sinus thrombosis could be considered in deteriorating cases despite anticoagulant therapy, but only few data are available. A systematic review of study on cerebral vein and dural sinus thrombosis found that a good outcome was reached in 22 of 25 patients treated with IV TL (rt-PA used only in 2 patients, 7,7%), even if a significant proportion of bleedings was reported [41].

The safety and efficacy of IV TL in dissection-related ischemic stroke was investigated in a recent prospective study coupled with comprehensive meta-analysis results. Data from a total of 39 stroke patients with cervical artery dissection suggested that thrombolysis is safe and functional recovery rates favourably compared with the overall IV TL efficacy reported in phase III trials [42].

Pregnancy was historically regarded as a contraindication to IV TL even if rt-PA is too large a molecule to cross the placenta and is not known to be teratogenic. To date, suggestions from literature are only limited to several small published case series and it is also debated whether IV TL or endovascular treatment be more appropriate in pregnancy. Major potential risks to mother and foetus are, aside from mother intracerebral haemorrhage, major uterine or foetus haemorrhage or spontaneous abortion. However they seem to be reasonably low in pregnancy and must be balanced against the potential of a disabled outcome without treatment. Hence, pregnancy should not be considered as an absolute contraindication to IV TL and the decision should be dependent on individual factors such as time from symptom

onset, imaging findings, other concomitant medical conditions or feasibility of an endovascular thrombectomy [43, 44].

ABSTRACT

Primary cerebral hemorrhage (ICH) is a major public health problem associated with a mortality rate of 40% in the first 30 days and case-disability rate until 80%. Clinical approaches for ICH varies from the aggressive surgery to the supportive medical care alone. Medical management of ICH should include controls of both blood pressure and intracranial pressure (ICP), osmotherapy, fever and glycemic controls, seizure therapy and multidisciplinary care in a specialized Stroke Unit. Overall, 15% of ICH are associated with anticoagulation use and in those, reverse therapy is recommended after monitoring the anticoagulation activity. Surgical therapy after ICH is effective in reducing mass effect, improving intracranial pressure and brain perfusion, preventing dangerous compartment shifts, as well as stopping the cascade responsible for secondary injury. in randomized trials there has been no reported advantage from surgery. However, Didecompressive hemicraniectomy (DHC) associated to haematoma evacuation and minimally invasive surgery could be useful in patients with ICH.

Keywords: cerebral hemorrhage, clinical management, reverse therapy, surgical therapy

INTRODUCTION: CAUSES AND NATURAL HISTORY

Primary cerebral hemorrhage (ICH) is a devastating disease with no established treatment and is therefore regarded as a major public health problem, giving rise to 10 to 15% of strokes in western countries and up to 30% in Asia [1]. ICH, described as spontaneous extravasation of blood into the brain parenchyma, is associated with a mortality rate of 40% and case-disability rates have been reported to reach 80%. ICH is classified as either primary or secondary. Hypertension is the most common (~65%) cause of spontaneous ICH, with other major causes being: amyloid angiopathy, brain tumors, aneurysms, arteriovenous malformations, cerebral cavernous malformations and arteriovenous fistulae [1]. ICH associated with the use of anticoagulants constitutes almost 15%, with a 7- to 10-fold increase in the risk of developing ICH from baseline [2]. Overall, 30% of ICHs are associated with antiplatelet use. ICH is classified into ganglionic (putamen, caudate and thalamus), lobar, cerebellar and pontine. The basal ganglia are affected in 40-50% of patients, cerebrum 20-50%, thalamus 10-15%, cerebellum 15% and brainstem less than 10% [3]. Their locations are correlated with outcomes and potential treatments and only the surgical decompression for cerebellar haemorrhages is widely accepted. Moreover, intraventricular bleeding has been reported to lead to poor prognosis. ICH prognosis is also associated to haemorrhagic volume, with half of all deaths occurring in the acute phase, especially in the first 48 h. Very large haemorrhages (>100 ml) are associated with a very poor prognosis [4]. Brain injury, mass effect and rim of edema are known to induce severe neurological deficits and death. Edema tends to increase rapidly after ICH, with a peak in the second week after stroke. The region around a hematoma is characterized by edema, apoptosis, necrosis, and inflammatory cells, which often leads to a secondary injury. Moreover, mass effect and physical disruption associated with the primary lesion, the response of the body/tissue to the hematoma (e.g., inflammation) and the release of clot components (e.g., haemoglobin/iron) may worsen the secondary injury [1]. These event phases could be targets for the treatment of ICH, which will be discussed in this chapter.

TREATMENT

No therapy has been reported to improved outcome in primary cerebral hemorrhage (ICH). Clinical approach for ICH varies from aggressive surgery to supportive medical care alone. Medical management of ICH should include controls of both blood pressure and intracranial pressure (ICP), osmotherapy, fever and glycemic controls, seizure therapy and multidisciplinary care in a specialized Stroke Unit or neurological intensive care unit (ICU); admission to the former seems to improve outcomes, while long stays in ICU seem to predict worse outcomes. Multidisciplinary team-care, together with more aggressive care seem to provide greater benefit to patients with ICH [5].

Medical Treatment

Elevated blood pressure (BP) is a common feature of acute ICH patients due to stress, pain, increased ICP, and premorbid acute or persistent elevations in BP. In fact, high BP has

been associated with greater hematoma expansion, neurological deterioration as well as higher rates of death and dependency after ICH [6]. For impaired cerebral blood flow autoregulation, excessive blood pressure reduction may exacerbate ischemia in the area surrounding hematoma and worsen neurological impairment. The American Heart Association Guidelines recommend aggressive infusion of antihypertensives including urapidil, labetalol, esmolol or nicardipine whenever systolic blood pressure (SBP) on admission exceeds 220 mmHg. While, for patients with SBP between 150 and 220 mm Hg on admission and without contraindications to acute BP treatment, an acute lowering of SBP to 140 mm Hg has been recommended by the INTERACT II study results [6]. Oral therapy is recommended for all patients regardless of BP, 24-72 h after infusion therapy or when a clinical condition has been stabilized [7].

Monitoring of ICP is recommended when an ICH patient is comatose (Glasgow Coma scale score <9), using external ventricular drain or fiber optic intraparenchymal control. Two other approaches for reducing ICP include positioning the head at a 30° angle and hyperventilation.

The phase III FAST trial (fVIIa for Acute Hemorrhagic Stroke Treatment) investigated for the efficacy of fVIIa in patients with ICH treated within 3 h of symptom onset. Of the 841 patients included in the study, 268 received placebo, 276 received 20 µg/kg, and 297 received 80 µg/kg of fVIIa; at 3 months the combined rates of death and disability were 24%, 26% and 29%, respectively. Mortality was similar among the groups. The rate of arterial thrombosis resulted higher in the group treated with 80 µg/kg of fVIIa (28%) compared to the placebo (18%) or 20 µg/kg of fVIIa (17%) groups. Thus, fVIIa did not lead to better functional outcomes, despite it being associated with a significant reduction in the rate of hematoma expansion [8]. The FAST trial subgroup analysis indicated possible benefit for patients under 70 years of age, those with baseline hematoma volumes less than 60 ml, those with baseline intraventricular hemorrhage volumes less than 5 ml and those with time from onset less than or equal to 2-5 h at admission [8].

Regarding the use of anti-edema, the administration of mannitol for 3-4 days in patients with ICH and neurological deterioration associated with high intracranial pressure or mass-effect, has been reported to improve functional recovery. Whereas, two randomized trials have reported no benefit from the regular use of intravenous mannitol boluses [9, 10].

Early clinical seizures (within 1 week), most often occur in young patients after ICH and they have been reported to be as high as 16%, with most occurring at or near onset. Clinical seizures should be treated with antiepileptic therapy, but prophylactic anti-seizure medication is not recommended [6].

Medical Care and Management of Complications

In a review of 1,421 patients with ICH, care limitations or withdrawal of life-sustaining interventions were the most common (68%) causes of death [11]. Airway management could be necessary in patients with ICH, but its benefit is generally offset by not being able to perform a thorough neurological examination; 10% of intensively treated patients will need the tracheostomy treatment for airway support, and early use of this approach might reduce the risk of aspiration and long-term mechanical ventilation.

About 30% of patients with ICH have stress gastric hemorrhages. Prophylactic H₂ blockers or proton pump inhibitor drugs are useful in decreasing the numbers of gastric events [12]. Moreover, in the first 2 weeks after onset, deep-venous thrombosis can be detected by ultrasonography in 20-40% of patients with pulmonary embolism risk. For these patients, low-molecular-weight heparin can be started on the second day after onset of intracerebral hemorrhage when the patients are neurologically stable. To this regard, a recent meta-analysis, including 1000 patients with acute hemorrhagic, comparing unfractionated heparin or low-molecular-weight heparin or heparinoids with treatments other than anticoagulants (elastic stockings, intermittent pneumatic compression or placebo), reported that early heparin prophylaxis for venous thromboembolism is associated with a significant reduction in pulmonary embolism, a non-significant reduction in deep venous thrombosis or death, and a non-significant increase in hematoma enlargement. In the studies included in this meta-analysis, anticoagulant therapy was started 24 h to 6 days from stroke onset [13]. Intermittent pneumatic compression (IPC) is an alternative treatment according to the results of Clots in Legs Or sTockings after Stroke (CLOTS) 3 trial. In this randomized controlled study, including 1,438 patients admitted to hospital within 3 days of acute stroke, IPC was both an effective and inexpensive method for reducing the risk of deep venous thrombosis and improving survival in immobile stroke patients [14]. However, only about 10% of the patients, had an intracranial hemorrhage in this study.

In the acute period of ICH, temperature and glucose controls with antipyretic medication and insulin infusion, are recommended due to the fact that hyperthermia and hyperglycemia both have neurotoxic effects.

Surgical Treatment

The surgical therapy after ICH is effective in reducing mass effect, improving intracranial pressure and brain perfusion, preventing dangerous compartment shifts, as well as stopping the cascade responsible for secondary injury [15]. In order to do so, general anesthesia and invasive craniotomy followed by dissection through viable brain to reach the hematoma need to be carried out. There is no standard protocol for hematoma removal and guidelines regarding evacuation are lacking.

The STICH I trial, which included 1,033 patients with both lobar and deep hemispheric ICH randomized to early surgery (within 96 hours of ictus) versus medical management with delayed surgery, reported a 10% relative increase in good outcomes in the surgical arm, but no benefit in 6-month favorable outcome (26%) compared with the medical arm (24%, $P = 0.41$) using the Glasgow Outcome Scale score. However, in a pre-specified subgroup analysis, subjects with lobar ICH ≤ 1 cm from the brain surface who underwent surgery had an 8% absolute increase in good outcomes compared with similar subjects in the medical arm [16]. This subgroup was subsequently investigated in STICH II [17]. In this randomized clinical trial, 601 patients with lobar hematomas of 10 to 100 mL located ≤ 1 cm from the brain surface and without intraventricular hemorrhage or coma were randomized to surgery versus initial medical management; 307 patients received surgery at a median of 26 hours after stroke onset. There was no advantage with surgery, because 41% of patients in the surgical group had a favorable outcome compared to 38% of patients in medical group. [17]. However, there was a trend toward lower 6-month mortality in surgical group compared to

medical group [15]. Furthermore, the STICH II authors performed a meta-analysis on 2,266 patients, observing an advantage for surgery therapy, but data were heterogeneous [17]. When cerebellar hemorrhages are greater than 3 cm, or when brainstem compression or hydrocephalus is suspected, surgery has been recommended by several non-randomized studies.

Open surgery to date, has failed to significantly improve the outcome of ICH patients, whereas less invasive approaches including microsurgery are now under evaluation in clinical trials.

INTRACEREBRAL HAEMORRHAGE DURING ANTICOAGULANT THERAPY

Worldwide, 15% of ICHs are associated to anticoagulation use. In fact, it has been reported that patients under anticoagulation treatment have a five-fold to ten-fold increased risk of ICH compared to the general population [18].

Antagonists

Hematoma expansion occurs in about 30% of patients with spontaneous ICH, but in up to 54% of patients with ICH associated with vitamin K antagonists. Use of warfarin increases the risk of progressing bleeding and mortality in patients with ICH. Being so, reverse therapy is recommended, even though a Canadian multicenter registry study has reported that both mortality and morbidity remained high [19]. For several decades, vitamin K alone was employed with the limitation that reversal therapy required more than 24 hours of therapy to fully reverse anticoagulation, even with intravenous administration at onset. In fact, the reversal effect of vitamin K alone begins around 2 hours after administration and reaches its maximum at 24 hours when liver function is normal [20].

The multicenter randomized trial 4F-PCC studied the use of prothrombin-complex concentrate (PCCs/Beriflex) versus fresh frozen plasma (FFP) for warfarin reversal in patients with ICH taking an oral vitamin K antagonist (INR > 2). The study reported the superiority of 4F-PCC over FFP regarding rapid INR reversal with the safety profiles being similar [21]. The ongoing FFP Versus PCC in Intracranial Hemorrhage trial is exploring the efficacy of these agents in spontaneous hemorrhagic stroke (NCT02429453).

In clinical practice, FFP, PCC or vitamin K are employed to reverse ICH in patients taking an oral vitamin K antagonist (INR > 2) [22-24]. However, the administration of FFP requires thawing and cross matching, carries a risk of allergic, infectious [6], and transfusion reactions, and often requires large volumes for full INR correction [6]. PCC on the other hand, does not require cross matching, can be reconstituted and administered rapidly in small volumes (20-40 mL), and has been successfully processed for inactive infection agents. Its principal limitation is that it can increase the risk of thrombotic events [21].

Being so, The European Heart Rhythm Association recommends that tranexamic acid, desmopressin or activated factor VII could be considered [25].

Direct Oral Anticoagulants (DOACS)

In the three large randomized trials on direct oral anticoagulants (DOACS), ARISTOTLE, RE-LY and ROCKET-AF [26], oral anticoagulants were reported to be associated with a lower risk of ICH, when compared to warfarin. However, the issue of avoiding hematoma growth, when patients with ICH are treated with DOACS has yet to be addressed adequately. Specifically, validated quantitative assays for monitoring the anticoagulant effect of DOACS need to be developed [27].

Monitoring the Anticoagulant Activity of DOACS

Normally, monitoring tests are not required for patients under treatment with DOACs. However, they could be useful in patients with ICH and stroke or those requiring emergency surgery [28]. In fact, the standard coagulation assays (aPTT, PT, TT), that are used to monitor heparin derivatives or vitamin K anticoagulants, may not accurately reflect the precise anticoagulant activity of DOACs [29]. Yet, these tests could be useful in clinical practice. Moreover, the activated specifically thromboplastin time (aPTT) is more responsive to dabigatran and an aPTT level two-fold greater than normal range 12 to 24 hour post-dose; which could suggest the presence of a dabigatran effect. Furthermore, aPTT test has high inter-individual and reagent variability, in fact 18% of patients taking dabigatran 150 mg twice daily have been reported to have a normal aPTT at trough [30]. The thrombin time (TT) is normal when no or minimal plasma dabigatran levels are present. A prolonged TT can be used to indicate the presence of dabigatran, but not its concentration, as the test has excessive sensitivity to dabigatran concentration. Dabigatran plasma concentration can be evaluated by Hemoclot thrombin inhibitors, ecarin clotting time and ecarin chromogenic assay [31]. Therapeutic levels of apixaban have shown essentially no effect on APTT and little effect on PT assays, whereas, rivaroxaban and edoxaban often elevate both the aPTT and the prothrombin time (PT) [31]. PT may provide a qualitative assessment for the presence of FXa inhibitors, but this data should be taken with caution [32]. Furthermore, anti-FXa assay might suggest anticoagulation effect absence [27]. To this regard, in an emergency setting, ex recommend, checking aPTT for dabigatran and PT for rivaroxaban and apixaban is recommended [33]. Concerning FEIBA it contains the vitamin-K dependent the factors II, IX, X, activated VII factor and protein C in non-activated form and reduces bleeding in dabigatran treated rats, but lower doses of FEIBA could reverse anticoagulant effect of rivaroxaban too [34]. Moreover, A study was conducted on 12 healthy volunteers receiving rivaroxaban (20 mg b.i.d) or dabigatran (150 mg b.i.d) for 2.5 days, followed by a bolus of 50 IU/kg of PCC, where the latter reversed the prolonged prothrombin time (PT) caused by rivaroxaban, but PT was not prolonged by dabigatran. Only the use of rFVIIa and FEIBA have been proposed after studies *in vitro* to reverse the anticoagulant effect of apixaban [27].

Dabigatran Reversal Agents

Antibodies to dabigatran (Idaruciximab) have been recently developed providing reverse effects within 1 minute of i.v. bolus injection in animal models and has structures comparable

thrombin, high affinities (350 times) for dabigatran and no activities in coagulation tests or platelet aggregation [35]. Idarucizumab administration in the absence of dabigatran has no reported effect on coagulation parameters or endogenous thrombin potential, suggesting that it is unlikely to be prothrombotic. The phase III trial REVERSE AD (NCT02104947) where idarucizumab was administered to patients with major bleeding or requiring emergency surgery, reported that it normalized both direct thrombin time and ecarin clotting time within minutes and was well-tolerated [36]. Moreover, the administration of intravenous fluids, the induction of diuresis and dialysis should be considered for patients on dabigatran, but not for those on apixaban or rivaroxaban.

Rivaroxaban Reversal Agents

PRT06445 (Portola compound or factor andexanet) is a truncated form of enzymatically inactive factor Xa that can reverse any of the Xa inhibitors [37]. In a phase 3 trial, andexanet immediately neutralized the anti-Xa activity of rivaroxaban in healthy elderly volunteers and resulted being well tolerated [38]. Another molecule under clinical development for reverse rivaroxaban activity is BAY1110262.

Apixaban and Edoxaban Reversal Agents

Andexanet reversal of apixaban with an IV bolus dose followed by a continuous infusion was administered to healthy elderly volunteers who were already taking 5 mg of apixaban twice daily [38]. No serious adverse or thrombotic events were reported.

PER 997 (Ciranparatag) is a small molecule that as been reported to reverse the anticoagulant effects of edoxaban, apixaban, dabigatran, rivaroxaban as well as unfractionated and low molecular weight heparin *in vitro* and in rats. As of 2016 Phase 3 trials are underway 2016 [39].

THERAPEUTIC STRATEGIES UNDERWAY

The effects of BP-lowering have been explored in two recent randomized clinical trials, ATACH II and INTERACT 2. The latter trial studied 2,839 patients with acute ICH and SBP between 150 and 220 mm Hg within 6 hours of ICH. Overall, 719/1,382 patients (52.0%) receiving intensive treatment (SBP target of <140 mm Hg within 1 hour of randomization and for 7 days, following protocols that included locally available intravenous agents) were compared with 785/1,412 patients (55.6%) receiving standard treatment (SBP <180 mm Hg). No significant effect of intensive BP-lowering treatment was observed regarding hematoma growth, but a modest benefit was seen in functional recovery in the BP-lowering treatment group [6]. ATACH II is now investigating the therapeutic benefit of the intensive treatment vs. standard treatment including death and disability (mRS 4-6) at 3 months in ICH patients treated 0-4.5 hours from symptom onset (NCT01176565).

A neuroprotective approach has been studied in animal models and results have indicated a decrease in brain edema after reducing the releases of iron, carbon monoxide or biliverdin from lysed red blood cell [40]. These results need to be confirmed in human trials.

The NXY-059 trial investigated the benefit from a 72-hour infusion of placebo or intravenous NXY-059, a free radical scavenger, within 6 hours of stroke onset in 607 ICH patients. The drug, when compared to placebo, lead to slightly less hematoma increase, but there were no observed effects on mortality or functional outcome in the patients taken the drug [41]. Additionally, the prior use of statins has been reported to have benefit in recent retrospective cohort studies [42]. Moreover, the principle trials on open surgery (craniotomy) in patients with ICH, both STICH I and II, have reported inconclusive results.

Regarding surgery, decompressive hemicraniectomy (DHC) is a neuro-surgical treatment that aims to decrease intracranial pressure (ICP) and is generally indicated for patients with ischemic or hemorrhagic stroke or those with traumatic brain lesions [43]. However, clinical benefits have been observed only for malignant middle cerebral artery infarction [44]. Experimental studies on animal models with ICH have observed that DHC reduces mortality, yet results regarding neurological outcomes have been controversial [45]. Regarding human studies, a recent review of literature including 191 patients with ICH volumes more than 60 ml, aged 40-60 years, and Glasgow Coma Scale scores less than 8 before surgery, observed favorable outcomes in 41% and average mortality of 21% [45] following DHC and hematoma evacuation. Another recent study, including a 51 patients series, undergoing a combination of DHC and hematoma evacuation, observed a significant midline-shift and an improved outcomes only in lobar ICH patients [46]. Limited data are available regarding clinical benefit from DHC without hematoma evacuation. In fact, studies to date have been small and often retrospective case series or case-control studies have been performed [42]. The SWITCH trial is currently comparing the best medical treatments in intracerebral hemorrhage against decompressive hemicraniectomy (NCT02258919). However, other surgical approaches are being explored as alternative for craniotomy. In view of the fact that MISTIE II and other pilot trials of minimally invasive surgery have shown to improve patient outcome, a phase III trial using this approach was started in late 2013. Minimally invasive surgery over conventional surgery includes some advantages: reduced operative time, possibility of local anesthesia and reduced local surgical trauma. Endoscopic aspiration has been suggested as a possible treatment for superficial supra-tentorial ICH, as it been shown to reduce mortality, especially in younger patients [47].

Finally, regarding thrombolysis, small studies have investigated on the benefits from, urokinase or tissue plasminogen activator (t-PA) in the treatment of intraventricular hemorrhage (IVH). Currently, the Phase III Clear IVH Trial is aiming to evaluate the efficacy and the safety of r-tPA in treating IVH (NCT00650858). Trials have assessed Factor VIIa versus placebo. STOP-IT is now evaluating the predictive value of spot-sign in the growth of ICH, and whether factor VIIa improve functional outcomes compared to placebo in these patients. Another ongoing trial is SPOTLIGHT (NCT01359202), which has the same aims and includes 15 Canadian centers.

Table 1. Assays and recommendations for reversal options of anticoagulants

	Half-Life (hours)	Monitoring Assay	Effective Reversal Strategies	Non-effective Reversal Strategies
Warfarin	40	PT	FPP, PCC, Vitamin K [6], Tranexamic acid, desmopressin, activated factor VII [24]	
Dabigatran	14-17	aPTT, TT, ECT, Hematoclot [25], ecarin-chemogenic assay	induction of diuresis, Dialysis, FEIBA [25], PER977 [48]	Vitamin K PCC rFVIIa
Rivaroxaban Edoxaban	5-9	Anti-FXa, PT, aPTT PiCT [26]	PCC, FEIBA [5], PER977 [45], PRT06445 (Lu G 2013).	rFVIIa Vitamin K Dialysis
Apixaban	9-14	Anti-FXa, mPT, HepTest [25]	rFVIIa, FEIBA [25], PER977 [45], PRT06445 [37].	Vitamin K Dialysis

PT: prothrombin time; aPTT: activated partial thromboplastin time; TT: thrombin time; ECT: ecarin clotting time; mPT: modified prothrombin time; PiCT: prothrombinase-induced clotting time; HEPTEST: heparin clotting test; PCC: prothrombin-complex concentrate.

ABSTRACT

Intracranial arterial stenosis (IAS), most often attributable to primary atherosclerosis, is the most common cause of stroke worldwide and is also associated with a high rate of recurrent stroke, even in patients receiving the best medical treatment. Severity of stenosis is the strongest predictor of stroke. The most commonly used therapeutic strategies for IAS include medical therapy, identification and control of risk factors and intervention to prevent thromboembolism and restore blood flow. High-resolution MRI, indirect revascularization technique (EDAS), precondition treatment and therapy with direct oral anticoagulants (DOACS) have been reported to provide benefits in both diagnosis and treatment of IAS. Future studies need to stratify large numbers of patients with IAS into subgroups according to the risk of recurrence and complications to deliver better treatment.

Keywords: intracranial stenosis, management, endovascular treatment

INTRODUCTION

Intracranial arterial stenosis (IAS) has been observed in 20-40% of patients with atherosclerotic disease and is associated with a risk of ipsilateral stroke of up to 7.6%

* Corresponding Author address: Maurizio Paciaroni, Stroke Unit and Division of Internal and Cardiovascular Medicine, University of Perugia, Santa Maria della Misericordia Hospital, Via G. Dottori 1, Perugia 06100, Italy. Email: maurizio.paciaroni@med.unipg.it. Tel and fax: (+) 39075.5782765.

annually. The currently available management options include medical treatment, risk factor interventions and surgical or intravascular treatments. The benefits from these options remain unclear [1].

EPIDEMIOLOGY AND PATHOLOGY

IAS is most often attributable to primary atherosclerosis, with other rare causes including embolic events, arterial dissection, vasculitis, infections, exposure to radiation, sickle cell disease and Moya-Moya disease [2]. IAS prevalence, evaluated by transcranial doppler ultrasound in asymptomatic Caucasian populations has been recorded to be 13%, whereas autopsy studies on the same groups have reported rates of up to 80% in those older than 80 years [3]. IAS has been primarily observed in Asian, Hispanic, Black and Indian populations, as well as in patients with vascular risk factors; suggesting racial and ethnic differences could be found in genetic susceptibility and lifestyle [4]. The reported proportion of patients with symptomatic intracranial stenosis among those hospitalized for ischemic cerebral was reported to be up to 50% in Asian populations [5]. Worldwide, IAS is the most common cause of stroke [6]: 10% of all reported strokes in USA [4] and 33-50% of all reported strokes in Asia [7]. Further, IAS is associated with a high rate of recurrent stroke, even in patients receiving the best medical treatment (higher in Blacks and women); the risk of stroke and death with IAS is disproportionally elevated in women, reported to be up to 29% [3]. Epidemiological studies have reported that Blacks with IAS have both an increased incidence and mortality from stroke, as well as stroke recurrence at an earlier age [8]. The WASID study reported that women had higher risks for both recurrent ischemic stroke and the combined end-point of stroke and vascular death, leading to an 85% higher risk of ischemic stroke for women when compared to men.

IAS is commonly hypothesized to be the result of a multifactorial process involving several risk factors leading to endothelial injury, lipid deposition on the arterial walls and inflammation. Metabolic syndrome, diabetes mellitus, abdominal obesity, hypertension and smoke are risk factors for endothelium injury and arterial atherosclerotic plaque. Multiple mechanisms alone or combined have been documented to be involved in the onset of ischemic stroke in patients with IAS: downstream ischemia, artery-to-artery emboli, local thrombosis and perforator vessel occlusion caused by plaque. The severity of stenosis is the strongest predictor of stroke [9]. In fact, the WASID study reported that severe stenosis $\geq 70\%$, was associated with a significantly higher subsequent risk of stroke in the territory of a symptomatic intracranial stenotic artery, compared to stenosis $< 70\%$; while it appeared to decline when stenosis was between 90% and 99% [9]. Also the presence or not of neurological symptoms has been correlated with different stroke risks: the rate of ischemic stroke has been reported to be 12% for symptomatic stenosis versus 3.5% for asymptomatic stenosis, at one year follow-up [10-11].

THERAPEUTIC STRATEGIES

There are Three commonly used therapeutic strategies for IAS: medical therapy, identification and control of risk factors and intervention to prevent thromboembolism and restore blood flow.

MEDICAL THERAPY

From 1955 until recently, the results from several retrospective studies had suggested that warfarin was more effective than aspirin in preventing progression of the disease and decreasing mortality, especially in the vertebral-basilar system. [12]. In 2005 the results of the WASID trial reported that when comparing aspirin (1200 mg/day) to warfarin in patients with symptomatic IAS over 1.8 years of follow-up, there was no observed difference between the two study arms for incidence of recurrent stroke, whereas warfarin was seen to increase both major hemorrhages and death. Furthermore, subgroups of patients with higher risk, such as those with severe stenosis (70-99%), vertebro-basilar stenosis and previous stroke symptoms was reported had no significant benefits from warfarin therapy.

In the CLAIR study (Clopidogrel Plus Aspirin for Infarction Reduction Study) [13], patients with IAS treated with the combination of aspirin and clopidogrel had lower rates of micro-embolic signals detected by transcranial Doppler until day 7, compared to patients receiving aspirin alone. The short-term use of aspirin plus clopidogrel, followed by aspirin alone, was also examined in the SAMMPRIS study. The study reported an overall 30 day rate of stroke or death equal to 5.8%. In the WASID study, patients with angiographically verified 50 to 99 percent stenosis of a major intracranial artery received warfarin or aspirin and the rate of stroke or death was observed as being 10.7% during a median follow-up of 14.7 months was recorded.

The WASID and SAMMPRIS trials also reported high annual rates of recurrent stroke in patients with IAS despite medical treatment: 15% [10] and 12.2%, respectively [1].

The Clopidogrel in High-risk patients with Acute Non-disabling Cerebrovascular Events (CHANCE) trial reported that the combined treatment of clopidogrel plus aspirin decreased the 90-day risk of stroke without increasing hemorrhage when compared to aspirin alone in patients with TIA or minor stroke [14]. Overall, 1,089 patients with MRA images available in CHANCE were included in a sub-analysis on the efficacy and safety of clopidogrel plus aspirin vs aspirin alone and found that 608 patients (55.8%) had IAS. In fact, patients with IAS had higher rates of recurrent stroke (12.5% vs 5.4%; $p < 0.0001$) at 90 days compared to those without IAS. There were no statistically significant differences observed between patients with and without IAS regarding primary outcome of any stroke (hazard ratio for clopidogrel plus aspirin vs aspirin alone: 0.79 [0.47-1.32] vs 1.12 [0.56-2.25]; interaction $p = 0.522$) and any bleeding event (interaction $p = 0.277$) [15].

The phosphodiesterase inhibitor cilostazol together with aspirin was seen to decrease the progression of intracranial stenosis, as measured by MRA and TCD at 6 months [16]. Cilostazol and clopidogrel were compared in a follow-up study on 457 patients with symptomatic middle cerebral or basilar artery and the number of new events (ischemic or hemorrhagic) at 7 months was similar between the two groups [17].

RISK FACTOR CONTROLS

Modifiable vascular risk factors for IAS include hypertension, smoking, diabetes, high total cholesterol concentration, low high-density lipoprotein cholesterol concentration and metabolic syndrome, while non-modifiable factors include race, age, certain angiotensin-converting enzyme polymorphisms, increased plasma endostatin/vascular endothelial growth factors and certain glutathione S-transferase omega-1 gene polymorphisms [18]. The WASID and SAMMPRIS trials examined the use of ACE inhibitors to decrease blood pressure and the use of statins to lower LDL-cholesterol concentrations. The WASID trial recommended maintaining blood pressure lower than 140 mmHg and cholesterol concentration inferior to 5-20 mmol/l [10]. In a trial on cilostazol in IAS (TOSS-2) [16] increased apolipoprotein B/A was associated with progression of stenosis, while increased HDL was associated with stable stenosis [19]. In the SAMMPRIS trial, the aggressive medical treatment arm, compared to the angioplasty and stenting arm, thoroughly monitored risk factors including blood pressure and LDL concentration. The identification and aggressive management of modifiable vascular risk factors is mandatory and systolic blood pressure should be kept ≤ 140 mmHg or ≤ 130 mmHg in patients with diabetes and low-density lipoprotein concentration should be maintained at <70 mg/dl [20-21].

SURGICAL TREATMENT

Limited surgical treatments have led to benefit in IAS. The International Cooperative Study of Extracranial to Intracranial (EC/IC) bypass trial, a prospective multicenter randomized trial, failed to report lower rates of stroke recurrence when comparing surgery to medical treatment in patients with extracranial occlusion or intracranial stenosis (EC/IC bypass Study Group 1985). The study enrolled 1,377 patients with extracranial carotid occlusion or intracranial carotid or middle cerebral artery stenosis, comparing the extracranial to intracranial bypass to aspirin treatment alone. Possible explanations for these study results could have been associated with the abrupt increase in the flow observed in the extracranial to intracranial bypass surgery, due to hypertension and hemorrhage and the competitive flow, which can trigger by the bypass which changes the flow and can lead creating stasis in the stenotic segment or adjacent segments [3]. The COSS trial compared extracranial-intracranial bypass to medical treatment, reporting that the 2-year stroke and death rate was not significantly better than that of the medical arm (21% versus 23%). The peri-procedural stroke rate in this trial was 15%, similar to that reported by the EC/IC bypass study. Bypass has been proposed for vertebro-basilar stenosis, but data regarding IAS cases are limited [22].

ENDOVASCULAR TREATMENT

In the 1980s endovascular treatment was considered a treatment option for intracranial stenosis, with its initial being promising [23]. Angioplasty alone resulted being complicated leading to a restenosis rate of up to 50% for treated patients and a high rate of vessel dissection [24]. For this, percutaneous angioplasty and stenting (PTAS) became the preferred

option for endovascular treatment, even though PTAS was known to have a high risk of peri-procedural stroke, due to the difficulty in navigating the intracranial vessels, trauma during balloon inflation and the deployment of the stents. In fact, PTAS was compared to aggressive medical treatment in patients with severe IAS in the SAMMPRIS trial, however the trial had to stopped prematurely (only 59% of planned patients had been enrolled) given that stroke or death occurred in 14% of patients in the angioplasty and stenting arm within the first 30 days, compared to 5.8% in the medical arm [1]. The 1-year rates of stroke and death were 20.0% for the PTAS arm and 12.2% for the medical arm, after a mean duration of follow-up of 11.9 months [1]. The SAMMPRIS trial results extinguished the enthusiasm for endovascular treatment in patients with IAS. The increased peri-procedural events were not due to operator inexperience [25], but instead more likely due to the elevated severity of the stenoses and/or the rigorous evaluation by local neurologists. Other studies have confirmed the results from SUMMPRIS [24]. In a review of literature on endovascular treatment in IAS, using the Wingspan stent system (self-expanding nitinol intracranial microstent) in association with the Gateway percutaneous transluminal angioplasty (PTA), it had already been tested in SAMMPRIS, which reported a combined risk of TIA and stroke of 6.2% for ipsilateral and a 9.5% risk for all territories [23]. Regarding possible risk factors, smoking habit was not significantly associated with peri-procedural stroke given that smoke habit increases the conversion of clopidogrel to an active metabolite. While, basilar artery stenosis, severity of stenosis, diabetes, older age and clopidogrel load were significantly associated to the presence of peri-procedural intracranial haemorrhages [26].

In-stent restenosis (ISR) is a serious complication, often symptomatic, observed in 3.3% of Gateway PTS balloon and Wingspan stent systems [23], caused by stimulation of intimal hyperplasia by the radial force of the stent. The Enterprise stent is a closed-cell intracranial self-expanding stent designed to reduce the incidence of in-stent restenosis, when compared to the Wingspan stent, it tends to reduce the radial force. A large series of patients treated with Enterprise stent reported the combined rate of neurological morbidity and death to be 7.7% at 30 days, while the rate of restenosis was in line with that observed for the Wingspan stent [27]. In coronary circulation, drug-eluting stents (DES) are commonly and successfully used to reduce the likelihood of restenosis, but single-center studies exploring DES application in intracranial stenosis have been conflicting [28-29]. The safety of DES in intracranial stenosis has not yet fully been established, due to repeatedly observed associations to high rates of technical failure and peri-procedural complications. Currently, the combined rate of morbidity and mortality is estimated to be 3.8% at 30 days [23]. Derived from the coronary approach, Balloon-Expandable stents (BESs), are also used in IAS: the combined rate of stroke and death at 30 days has been estimated at 23.9%, whereas the majority of these strokes were severe (13%) [23]. The most frequently observed complication is thromboembolism which can cause downstream vascular occlusion. Patients with stented basilar arteries have been reported to experience a high rate of perforator territory infarcts, [25]. As well, dissection of the vessel is frequent for anatomical reasons including the mobile position of cerebral artery in the subarachnoid space and the tortuous course of cerebral arteries. Other complications can include restenosis and vascular perforation as well as vessel rupture.

ALTERNATIVE PERSPECTIVES

Future studies are needed to stratify large numbers of patients with IAS into subgroups according to the risk of recurrence and complications in order to relize targeted therapeutic strategies. Specifically, high-resolution MRI, using 3 tesla or higher magnets, could be reccommandable to best suited for characterizing IAS, leading to a better description on the states of the stenosis, lumen and vessel walls; therein assisting in the prediction of any critical stenosis [30].

The indirect revascularization technique (EDAS), which involves the transposition of a segment of a scalp artery into the surface of the brain without a direct anastomosis, has been used in treating Moya-Moya disease. In comparison to direct revascularization, EDAS is less technically demanding, as it does not require the temporary occlusion of cerebral vessels and allows for a gradual development of revascularization only where the brain requires it. This surgical treatment has been tested in IAS with contrasting results [31].

Brief limb ischemia seems to confer systemic protection against myocardium infarction in humans and in animal models; emerging data suggest the same protection ("ischemic preconditioning") might be useful in stroke for cerebral tissue [32]. Meng et al. have reported a decrease in new events in a trial including 68 patients treated with brief repetitive bilateral arm ischemic preconditioning (occlusion of both brachial arteries with a blood pressure cuff twice daily for 300 days) [33].

Trials assessing benefit and safety from direct oral anticoagulants (DOACS) are underway following a prospective study reporting that treatment with acenocoumarol, adjusted to maintain internal normalized ratio (INR) between 2 and 3, decreases the risk of recurrence by reducing the progression of intracranial stenosis [34]. Moreover, oral anticoagulants may play an important role in preventing the deposition of new thrombotic material on the artery stenotic walls, however, according to WASID study, warfarin was seen to increase both major hemorrhages and death compared to aspirin. Therein, DOACS could be considered a safe alternative treatment to warfarin in reducing progression of IAS, given that they have been associated with a significant reduction in intracranial bleedings compared to warfarin use.

Chapter 31

“TELESTROKE,” A FRONTIER IN THE GLOBALIZATION ERA

C. M. Klingner*, MD, O. W. Witte, MD and A. Günther, MD

Hans Berger Department of Neurology,
Jena University Hospital, Jena, Germany

ABSTRACT

Stroke telemedicine (or telestroke) allows the delivery of neurological expertise to remote locations with limited access to neurological care. Current telestroke networks are steadily growing, mainly to support emergency department consultations. These consultations are focused on the hyperacute treatment of stroke patients with rt-PA.

Most telestroke programs use a combination of interactive video conferencing and teleradiology to support the quality of their consultations. These telestroke networks have been demonstrated to increase the rate of thrombolytic treatment, reduce patient hospital stays and improve functional outcomes. From a macroeconomic perspective, telestroke is also cost efficient because the costs are overcompensated by the savings that result from the increased number of patients who are discharged home and the reduced costs of long-term care.

Despite convincing evidence of the effectiveness of telestroke, worldwide, there are limited options for reimbursement for telestroke networks, which is seen as a major barrier to the growth and sustainability of telestroke networks. Nevertheless, the last 12 years have seen the rise of telestroke networks, enabling access to state-of-the-art conservative acute stroke therapies regardless of geographical location.

Although teleneurology is currently mostly used for acute stroke treatment, it is likely that it will become incorporated into other aspects of neurological care, such as stroke telerehabilitation or prehospital telestroke.

This chapter reviews the development, current status, problems and perspectives of telestroke from a global perspective.

INTRODUCTION

With the agricultural and industrial revolution in the late 19th century, the relatively stable equilibrium between rural and urban populations broke due to unprecedented growth in urban residents. Today, more than 50% of the world's population lives in cities.

In general, the range of offered services is much greater in urban regions compared to rural locations. This principle holds also true for the medical sector. Rural locations with a low number of inhabitants obtain their emergency medical services mostly at small country hospitals. These hospitals often have less than 100 beds and normally do not have a neurology department. Patients who cannot be treated in such hospitals are shipped to the next urban hospital that offers the required expertise.

Although this structural organization is economically and clinically reasonable, it is problematic for stroke patients. With the approval of intravenous recombinant tissue-type plasminogen activator (rt-PA) by the Federal Drug Administration in 1996, there is a potent treatment for acute ischemic stroke available, and it is beyond doubt that swift initiation of treatment is strongly beneficial to stroke patients [1, 2]. However, the American Heart Association estimates that less than 5% of all ischemic stroke patients in the USA are treated with rt-PA. They further reported that only approximately 50% of patients have access to primary stroke centers within a drive time of 60 min, and half of all hospitals have no staff neurologists [3, 4]. These are some of the reasons that cause a reduction in the application of rt-PA in small and rural hospitals. A recent study has estimated that the chance for a patient to receive rt-PA is tenfold less in a rural emergency department compared to an urban primary stroke center [4].

An analysis of the MEDPAR database revealed that from 2005-2007, 64% of US hospitals did not use rt-PA [5]. Some of these smaller hospitals used a “ship and drip” model, in which a patient with a suspected stroke is shipped to an urban hospital before receiving intravenous rt-PA (drip). This procedure wastes valuable time, and often, rt-PA cannot be administered in the urban hospital due to the now lapsed time window for rt-PA treatment.

Studies have identified pre-hospital as well as in-hospital barriers to the delivery of thrombolysis for acute stroke [6, 7]. One of the most important in-hospital barriers is physician uncertainty in administering rt-PA and concern about the adverse effects of rt-PA [6]. The uncertainty and concern is caused by the very complicated and restricted indications for rt-PA. There are 26 formally listed contraindications for rt-PA. However, it is insufficient to know these contraindications because there are a multitude of studies available that have investigated these contraindications as well as their importance and risk characteristics. Each of these contraindications has to be weighed for each individual patient with respect to his/her risk-benefit ratio. Moreover, the recently published intervention studies of additional or (in the case of specific contraindications) alternative methods make the decision even more complicated [8-11]. However, the decision for or against thrombolytic therapy has to be made quickly because the therapeutic effect of rt-PA is highly time dependent. Incorrect decisions

can cause severe adverse effects and even the death of the patient. The natural reflex of most physicians is that it is better to do nothing than to do something wrong.

Accordingly, stroke patients are in need of acute neurological stroke expertise in local hospitals. This need is targeted by telestroke networks. By way of modern communication technologies, these networks bring stroke expertise to rural locations when it is needed.

However, there are also some problems with telestroke, such as reimbursement for the use of telestroke networks, licensing and accreditation issues as well as technological problems.

This chapter reviews the development, current status, problems and perspectives of telestroke from a global perspective.

HISTORY

The Beginning of Telemedicine

The idea of delivering health care through telecommunication is so obvious that telemedicine has effectively existed as long as telecommunication. As an early precursor, African villages used smoke signals in cases of serious disease to warn people to stay away from that village. The invention of the telephone in the nineteenth century marked the beginning of modern telemedicine. In 1906, the first electrocardiogram trace was transmitted using telephone cables. A further example is the Australian outback, where people used 2-way radios to communicate with the Australian Royal Flying Doctor Service in the 1930s. With the rise of radiological imaging, telemedicine became more technically demanding. The earliest reference in the medical literature describing the transmission of radiological images was published in 1950 [12]. This was called “Telognosis,” which was a combination of the three terms “teleo roentgen diagnosis.” Although this term did not achieve mainstream use, it marked the beginning of remote medical image transmission. The term “Telemedicine” was not introduced in the medical literature until the study of R.G. Mark was published in 1972 [13]. During the next decade, Canadian radiologists at Montreal’s Jean-Talon hospital created a teleradiology system [14].

A major influence on the development of telemedicine originated from developments in the manned space-flight program. Physicians at the National Aeronautics and Space Administration (NASA) were concerned about the effects of zero gravity on astronauts. To monitor the physiological functions of the astronauts, sophisticated biomedical telecommunication systems were developed [15]. Moreover, plans needed to be developed in case of a medical emergency. Such an emergency in space parallels emergencies in rural locations on Earth. In both cases, people with significant health problems have difficulty accessing appropriate health care. Within the space program, telemedicine was further developed within the STARPAHC (Space Technology Applied to Rural Papago Advanced Health Care) program that was sponsored by NASA and designed by Lockheed Missiles and Space Corporation during the 1970s. The program used the most advanced technology to explore the possibilities of providing improved health care to a remote population in southern Arizona via telecommunication [16-17].

In addition to the space program, the development of television was the second major influence on telemedicine at this time. In the year 1959, a neurological examination was transmitted by the use of two-way interactive television to students at the University of Nebraska [18]. This technology was further developed and applied to medical consultations in 1964. A two-way television link was established between the University of Nebraska and Norfolk State Hospital to provide case consultations, medical examinations and speech therapy [14]. In the late 1960s and early 1970s, multiple telemedicine projects were funded by the US federal government to determine the feasibility and capabilities of telemedicine systems. These systems were further developed in the next decades and were applied in multiple medical disciplines.

The Development of Telestroke

Within the discipline of neurology, telemedicine has received increasing attention after the Food and Drug Administration approved the use of rt-PA for acute stroke in 1996. However, the indications for this drug were (and are) difficult, and many contraindications have to be considered. This has led to a divergence in the use of rt-PA between specialized urban stroke centers and small rural hospitals. An analysis of the MEDPAR database revealed that between 2005-2007, 64% of US hospitals did not use rt-PA [5]. Some of these smaller hospitals used a “ship and drip” model, in which a patient with a suspected stroke is shipped to an urban hospital before receiving intravenous rt-PA (drip). This procedure wastes valuable time, and often, rt-PA cannot be administered in the urban hospital due to the now exceeded time window for rt-PA treatment.

Due to these problems, the use of telemedicine for the hyperacute treatment of stroke patients with rt-PA was discussed [19]. In 1997, the University of Iowa received funding from the National Library of Medicine to develop telemedicine for stroke in rural areas [19, 20]. Additionally, several states were awarded grants by the Department of Health and Human Services (HHS) over the years 1997-1999 for several different rural pilot telemedicine projects.

The first telehealth applications dedicated to treat stroke patients in remote hospitals were developed by the Department of Neurology of the Medical College of Georgia in 2001 [21-23]. This development led to the launch of the REACH system in 2003, which enabled the examination of patients at rural hospitals [21-23]. The REACH system consisted of a mobile cart that was located at the rural emergency department. It captured video images and data that were transferred to the hub hospital in Georgia via an internet connection. The data transfer was compliant with Health Information Portability and Accountability Act requirements. This system enabled the performance of NIHSS evaluations and the review of the brain imaging [21]. Over the first two years, this system was used for 194 acute stroke consults, of which 30 patients received rt-PA. This pilot study demonstrated that the use of rt-PA in rural community-based hospitals was possible. The door-to-needle time improved from 98 minutes in the first year to 78 minutes in the second year. In subsequent years, multiple other technical solutions dedicated to the requirements of telestroke networks were developed.

Over the last decade, the use of telestroke systems has increased. A Canadian survey in 2006 identified 12 telestroke networks [24], while in 2009, the American Heart Association

found 33 organizations that provide telestroke services [25]. In 2012, 97 potential telestroke networks were identified in the US alone, of which 56 were active [3].

IMPLEMENTATIONS

Technology Issues

In our own experience as well as from reports of other telestroke networks, there are a number of technical issues that have to be addressed during the implementation and maintenance of a telestroke network. First, the total cost of initiating a telestroke network is generally borne by the hub hospital. Spoke hospitals tend to participate in telestroke networks only if they are not required to pay for the technical equipment.

Soon after the implementation of telestroke networks, the equipment has to be maintained by the hub and spoke IT staff. The general lack of IT staff in spoke hospitals turned out to be a problem [26]. Currently, multiple vendors are available that offer professional and less maintenance-intensive systems. The vendors normally take care of the maintenance, repair and modernization of the telestroke equipment (e.g., Polycom, REACH Call, Tandberg, InTouch Health, and MEYTEC).

A further issue is the security of data. The information technology used must carefully control access to the telestroke data. In the US, data transfer must be compliant with Health Information Portability and Accountability Act requirements.

Modern telestroke equipment also integrates methods to store and communicate consultation findings. However, such a dedicated telemedicine software package is used in only 44% of US networks [3]. Alternatives include the use of paper, typing or the dictation of consultation findings [3].

Organizational Elements of Telestroke Networks

Before the implementation of a telestroke network, some important points must be considered. First of all, there have to be a need for the telestroke service, i.e., there must be small rural hospitals without a neurology department within the area surrounding the hub hospital. In the USA, most spokes are rural hospitals with fewer than 100 beds [3]. It should be further noted that the efficiency of a stroke network increases with the number of spokes [27, 28]. From a macroeconomic perspective, there should be at least 4 spokes associated with a telestroke network [27, 28]. In a survey from 2009, a mean number of spokes per hub of 7.6 was found, which was a significant increase over the mean for the years 2008 and 2007 [3]. The maximum number of spokes was found to be 28 [3].

The service offered and reimbursement model should also be further discussed. In particular, the service chosen might influence the possible reimbursement models. For example, two-way interactive video is often a requirement for any US federal and state reimbursement. A further question is whether brain imaging should be reviewed as part of the consultation process. However, the implementation of a new telestroke network that lacks the review of brain imaging or two-way interactive video can be seen as outdated, as in 2010,

94% of all (responding) US telestroke networks used both methods as part of their consultation process [3]. There are a multitude of vendors available that offer software and hardware for each aspect of telestroke service. Most telestroke implementations use the telestroke solutions of one vendor; ~20% of sites use a hybrid solution that combines the products of more than one vendor. The choice of one vendor for the whole telestroke solution is also highly recommended based on the experience of the authors, as technical incompatibilities and failures can represent a considerable drawback with respect to the confidence of the spoke hospitals in the telestroke network.

Additionally, some telestroke programs also offer a telephone-only consultation if needed. The composition and size of the telestroke team varies depending on the resources available at the hub. However, because 24/7 availability is highly needed, the personal and financial resources of the hub must be above a critical mass. This is especially true because most hubs provide neurology specialists from among their own personnel; only ~25% of the telestroke networks use outside-contracted specialists as part of the telestroke team. In all telestroke hubs, a physician is included. However, some programs also incorporate nurses or physician assistants [3].

The implementation of a telestroke network at the hub requires formal contracts or at least memoranda of understanding with spoke hospitals regarding consultation fees, equipment maintenance costs, data encryption and privacy.

Figure 1. Telestroke in acute stroke treatment. The stroke expert has to decide whether the patient should be treated with intravenous rt-PA. The thrombolytic therapy is then given in the rural hospital. The stroke expert then has to decide whether there is a reason to ship the patient to the hub hospital. Such reasons might include, for example, the need for a neuroradiologic intervention in the case of a proximal vessel occlusion or increased intracranial pressure. If there are no reasons to ship, than the patient should be further treated in the rural hospital.

Telestroke-Associated Clinical Process of Care

There are multiple studies available reporting the successful performance of clinical processes and decision making for stroke thrombolysis in acute stroke by telemedicine [3, 4, 29-32]. The typical clinical process of care after patients arrival at a telestroke-associated emergency department is started after a stroke is suspected as a possible cause of symptoms. This initial step has to be performed by the physician at the local emergency department. In most telestroke networks, the clinical assessment of symptoms is quantified using the National Institutes of Health Stroke Scale (NIHSS). This score has shown high reliability and reproducibility in measuring neurological disability in stroke and has further shown high inter-rater reliability between a bedside examination and a remote examination using a telestroke network [21, 33, 34]. It was further demonstrated that assessment of the NIHSS by an experienced neurologist can be reproduced by non-neurologists and that the NIHSS is even robust when evaluated via prehospital assessment by a video cell phone [35-37]. The NIHSS score should be used to allow for comparisons with the current stroke studies that use this score.

After patient examination and NIHSS assessment, the evaluation of acute stroke brain imaging is the next fundamental step in telemedicine-based evaluation of the indication for stroke thrombolysis. Similar to the NIHSS score, teleradiological review of brain imaging also exhibits a high level of agreement. A recent study investigating the presence or absence of radiological contraindications to thrombolysis found an overall agreement of 91% between spoke radiologist, hub vascular neurologist and hub neuroradiologist [38]. A further study investigating the reliability of cerebral CT evaluation of early ischemic changes in 536 patients by stroke neurologists detected discrepant CT findings in 8%, while clinically relevant discrepancies were found in only 1.7% [39]. Accordingly, the American Stroke Association (ASA) guidelines recommend the use of teleradiology systems for timely review of brain CT and MRI scans in patients with a suspected stroke [40].

After evaluation of the patient and brain imaging, the hub hospital is notified and the on-call neurologist is connected. The patient is moved to a room containing the telestroke equipment while a nurse enters the patient's information into the system. The remote neurologist obtains the NIHSS score using real-time video assessment, views the brain imaging results and reviews the laboratory data if available. Thereafter, the remote neurologist makes his decision about the appropriateness of rt-PA administration and gives his recommendation to the local physician.

Prehospital Telestroke

Due to the small therapeutic window for rt-PA thrombolysis, strong efforts have been made to reduce the time between symptom onset and the start of the thrombolytic therapy.

Specific barriers were identified to the delivery of stroke thrombolysis, mainly at the hospital level, and removal of these barriers resulted in increased thrombolysis administration [41-43]. However, to minimize the time between onset of symptoms and treatment, the pre-hospital stroke management also has to be optimized [44]. The prehospital elements of the stroke treatment chain are more difficult for neurologists to influence because they are not under the control of stroke experts. Previous attempts to optimize the prehospital procedure

involved attempts to improve prehospital recognition of strokes by the use of stroke scales [45-47] and pre-notification of the emergency department about an impending stroke [48-51].

Beyond the use of stroke scales, it was hypothesized that diagnostic accuracy in prehospital settings could be improved if the examination was remotely performed by a hospital-based physician via video teleconferencing. Two studies of actors who simulated stroke symptoms in ambulances produced diverging results [52, 53]. While the first study found the evaluation of stroke neurological deficits to be valid and reliable and further found shortened treatment times [52], eight years later, the second study reported that prehospital telestroke examinations were not at a level acceptable for clinical use [53]. However, it is important to note that the negative result was mainly caused by problems in data transmission, which tends to be a problem for moving objects within current mobile communication technology networks. A further study has addressed this problem by bundling multiple 3G lines [54]. While it demonstrated the feasibility of prehospital teleconsultation, this study failed to demonstrate its superiority over regular EMS care [54].

Attempts to further optimize rt-PA treatment times have led to a system that provides a complete hyperacute stroke work-up preclinically by installing a point-of-care laboratory and a CT scanner into an ambulance (German Mobile Stroke Unit (MSU) and Stroke Emergency Mobile (STEMO)) [44, 55-57]. The CT images were transferred to the hospital for teleradiological evaluation [55, 58]. To provide the costly service of the STEMO in an efficient manner, it operates in a metropolitan area (Berlin) on patients who have been preselected using stroke identification algorithms during emergency calls [59-61]. In this setting, the STEMO has been demonstrated to decrease time to treatment without an increase in adverse events [44]. A particularly interesting point is that the STEMO ambulances are staffed by experienced neurologists trained in emergency medicine. Therefore, the video teleconferencing system available in the STEMO ambulances is not generally needed, but this capability might become important if ambulance-based thrombolytic therapy is performed without an on-board neurologist. However, the selection of the neurologists that staff the STEMO might introduce a slight bias, as one might speculate that the same neurologists might also exhibit above-average performance within a hospital. In our experience, the implemented stroke protocols are a major factor for the quality, speed and security of hyperacute stroke therapy, but these factors also depend on the experience and work load of the attending neurologist.

A similar Mobile Stroke Unit project was recently launched in the US [62]. During the 8 week run-in phase, ~2 patients per week were treated with rt-PA [62].

Telemedicine in Stroke Rehabilitation

Stroke is the most common cause of acquired disability. Stroke symptoms are dependent on the location of the brain damage and often affect motor function, speech, vision, cognition and sensation. It was estimated that 25% to 74% of stroke survivors require some degree of assistance or are fully dependent on caregivers for activities of daily living [63]. In particular, motor impairments were found to be the most critical factor influencing the patient's ability to live independently [64, 65]. While acute stroke treatment targets the prevention of further brain damage, stroke rehabilitation is able to achieve better recovery in terms of bodily

functions and activities of daily living to reduce disability and handicap during the following years [66].

As part of the post-acute stage, stroke rehabilitation is usually provided by healthcare professionals in a hospital or clinic setting and is often lengthy and resource intensive. Stroke telerehabilitation attempts to provide the same type of rehabilitation by an alternative method that does not require people to leave their homes. This constitutes the key advantage of telerehabilitation, which offers rehabilitation opportunities to people in remote areas that lack easy access to rehabilitation teams with expertise in stroke. It also reduces the burden of traveling long distances for people with severely restricted mobility. Additionally, telerehabilitation can be used to complement and enhance existing rehabilitation services. It might be possible to discharge patients from the clinical setting earlier and continue the rehabilitation process by telerehabilitation. In particular, long-term stroke care is considered underdeveloped, and many stroke survivors complain about a lack of intense, specialized rehabilitation after discharge from the rehabilitation clinic [67]. It is hypothesized that telerehabilitation might be a more convenient and less expensive means of rehabilitation after stroke. Despite the obvious advantages, there are considerable challenges associated with telerehabilitation [68]. The key issue is how to conduct assessments and treatments that need to be manually performed by the therapist? This shortcoming requires a modification of current techniques that do not need the “hands-on” support of the therapist [69]. A further question concerns the most appropriate form of communication between the rehabilitation professional and the patient [70].

There are multiple studies available that have investigated the effectiveness of stroke telerehabilitation and whether it improves outcomes. The mechanisms that lead to recovery are the same in conventional and telerehabilitation. Improvements in function during rehabilitation can be attributed to a combination of physiological recovery, neuroplasticity and compensation [71]. Therefore, the results of telerehabilitation can be directly compared with those of conventional rehabilitation strategies.

Most studies investigated the effects of telerehabilitation on motor function [72-77]. The training was performed at the patient’s home. These studies used customized computer-based training programs to improve the function of the upper [72, 75-77] or lower limbs [74]. A multitude of outcome measures were assessed, including physical function, independence in activities of daily living, quality of life and participant satisfaction. Some studies also assessed outcomes using a follow-up design [72, 73, 76]. All studies supplied the participants with the necessary video-conferencing hard- and software.

Most of the available studies compared telerehabilitation with an alternative intervention [75-77]. For example, Piron et al. used a virtual reality-based system to provide motor tasks to patients for 4 weeks [76]. This intervention was compared with traditional physical therapy. Both strategies were found to be effective, while the telemedicine intervention produced better outcomes in motor performance [76]. The same group investigated the satisfaction and improvements of patients undergoing a virtual reality therapy program at home compared with the same program in a hospital setting [77]. The authors reported significant improvements in motor function only in the telerehabilitation group and not in the group that trained in the hospital setting. Moreover, the group that received telerehabilitation showed a higher degree of satisfaction [77].

A further study compared the so-called Home Care Activity Desk training in a home setting with “usual care,” demonstrating no significant differences [75].

There are two studies available that compared two different telerehabilitation training strategies (repetitive tracking movements versus repetitive simple random movements) [72, 74]. One of these studies did not find a clear advantage of the tracking training over the same amount of practice of random movements after two weeks of training [72], while the other study found a significant advantage of the tracking training after 4 weeks of training [74].

A further study used a combination of technologies (video recordings, in-home messaging and phone calls) to compare functional mobility with “usual care” and found no significant differences between the groups [73].

Despite the availability of multiple investigations of the effectiveness of telerehabilitation, comprehensive studies that provide evidence of its effectiveness are still lacking [78, 79]. The reasons for this include the complexity and heterogeneity of stroke symptoms; the lack of robustness of the research methodologies used, which causes an insufficient ability to capture changes that are relevant to the treatment evaluated; and an often small sample size, which does not allow reliable data interpretation.

To date, there are also no studies available that have investigated the cost-effectiveness of telerehabilitation after stroke [79].

Motivations for Implementing Telestroke Programs

In the USA, only approximately 50% of patients have access to primary stroke centers within a drive time of 60 min, and half of all hospitals have no staff neurologists [3, 4]. A recent study estimated that the chance a patient will receive rt-PA is tenfold less in a rural emergency department compared to an urban primary stroke center [4].

Accordingly, the motivations to implement a stroke network are mainly to provide a community benefit, to improve clinical outcomes and process effectiveness and to provide knowledge [3]. A further driving force for hub hospitals to implement a telestroke network is that the hospitals likely already receive calls for help with patients, and it is generally very difficult to manage cases and indicate transfer to the hub without knowing whether there is indeed a neurological necessity.

Interestingly, revenue enhancements, cost reduction and bed management were among the lowest-ranking reasons to create or participate in a telestroke program [3]. However, these data were collected mainly from the physicians participating in the program, whereas the decision to create or participate in a program are made within the administrative hierarchy of a hospital, and such administrators did not participate in the cited survey [3]. Therefore, these results likely did not reveal the whole picture.

Barriers to the Initiation, Growth and Sustainability of Telestroke Programs

A survey of active telemedicine programs in the USA in 2009 identified 56 programs.

A survey of telestroke programs in the USA between 2000 and 2009 showed that the mean operating duration of the networks was 2.4 years [3]. The most important barriers to growth and sustainability were a lack of funds and a lack of reimbursement, respectively [3, 26, 80].

One possible solution is to increase the value associated with the treatment of acute ischemic stroke with thrombolysis (US: DRG 559). However, previous increases in this DRG were primarily due to the medication costs of rt-PA and not to possible increases in diagnostic and personnel efforts with these patients. In particular, the possibility of a telestroke consultation is not represented by this DRG. This is particularly illustrated by the fact that when a patient receives rt-PA in a spoke hospital and is then transferred to the hub, neither hospital receives this increased DRG [29, 80-82].

Also the inability to obtain physician licensure has been reported as an important barrier [3]. In particular, the lack of funds and a lack of technological support were the main barriers for spokes.

Malpractice protection is also an important barrier to the initiation and maintenance of telestroke programs. This, however, is a special problem in the USA. In most European countries, where the financial consequences of malpractice are more moderate, this did not constitute a relevant barrier.

CLINICAL EFFECTIVENESS

Participants

Pooled data analyses have clearly demonstrated that swift initiation of thrombolytic treatment with rt-PA is strongly beneficial to stroke patients [1, 2]. The therapeutic benefit of rt-PA is time dependent and is greatest when it is administered soon after stroke onset; its efficacy diminishes when it is administered at ≥ 4.5 hours post-onset [83-86]. The sensitivity of brain tissue to ischemia causes this time dependence of the effectiveness of rt-PA. Accordingly, the number needed to treat (NNT) for one patient to recover (mRS 0-1) increases with time (<1.5 h NNT=5; 1.5 h-3 h NNT=9; 3 h-4.5 h NNT=15) [86-88]. Adverse events are also time dependent; patients with earlier stroke onset-to-treatment times experience reduced symptomatic intracranial hemorrhage and a reduced likelihood of death [89]. Therefore, it is crucial to minimize the time between the onset of symptoms and treatment. For every 15-minute reduction of door-to-needle time, there is a 5% lower chance of in-hospital mortality [1, 2]. According to current guidelines, a door-to-needle time of 60 minutes is the official goal for treatment of ischemic stroke [40, 90]. In the US, the overall rate of stroke thrombolysis is <5%, and only 26.6% of patients who arrive in time to be treated with t-PA receive that medication within an hour after arrival, demonstrating the significance of in-hospital delays [2]. Some other hospitals have shown that improvements in the acute stroke management can reduce the door-to-needle time down to 20 minutes [43, 91]. There are also case reports that have demonstrated that under optimal circumstances, the door-to-needle time can be further reduced (down to 7 minutes) [92].

These data highlight that there is considerable room to optimize door-to-needle times. Factors that improve door-to-needle time include advance hospital notification by emergency medical services, fast access to a CCT, storage and administration of rt-PA in the emergency department, and full-time availability of an in-house stroke expert [93]. This requires the optimization of prehospital [44] and in-hospital stroke management as well as extensive

knowledge about the indications and contraindications for rt-PA. The optimization of stroke care is particularly difficult if few strokes occur and no in-house neurologists are available.

It is therefore probable that the addition of a consultation with a stroke expert via a telestroke network might accelerate the decision process and improve the quality of decisions. However, the costs and effort required to initiate and maintain a telestroke network have to be justified by evidence of benefit.

While most telestroke networks measure and evaluate the clinical quality of their programs [3], there are no randomized studies available that have investigated the influence of telestroke medicine on the functional outcomes of stroke patients. However, some non-randomized studies have investigated the clinical outcomes of patients [94-97].

One German study used a non-randomized design to compare 5 community hospitals that were included in a single telestroke network with 5 matched community hospitals that were not included in any telestroke network [94]. Within 2 years, 3122 patients were included. The main finding was a reduced rate ($p < 0.0001$) of patients with a poor outcome (44%) in spoke hospitals compared with the rate of 54% for patients treated in the control hospitals. A poor outcome was defined as an mRS > 3 , a Barthel index < 60 or institutional care or death after 3 months. The spoke hospitals demonstrated improved performance on a set of predefined measures of the quality of acute stroke care (e.g., diagnostic procedures, thrombolytic treatment (5% vs. 0%), physiotherapy, speech therapy). The length of stay in the hospital was significantly reduced in the spoke hospitals [94]. This study was complemented by a follow-up investigation of outcomes after 12 and 30 months, which showed that the patients treated in spoke hospitals exhibited significantly lower rates of death and dependency [96].

Another study compared the functional outcomes of patients treated with rt-PA between a spoke hospital and the hub and found no significant differences in functional outcomes after 3 and 6 months. The results were similar to those of the available randomized trials [98]. Similar results were obtained by a Finnish study [97], which also compared the functional outcomes (mRS) of rt-PA-treated stroke patients in spoke hospitals with the outcome of patients treated in the hub [97]. This study found a favorable outcome (mRS 0-2) in 49.1% (spoke) vs. 58.1% (hub) and symptomatic intracerebral bleeding in 6.7% (spoke) vs. 9.4% (hub). An interesting feature of this study was the high percentage of consultations that led to thrombolytic treatment (57.5%) [97]. Other studies have found rates of consultations that lead to thrombolytic treatment of 8.8% [94], 15.5% [23], 25% [99] and 29.8% [94]. The high rate of thrombolytic treatment compared to the number of consultations in the Finnish study indicates either a reluctant indication for a telemedicine consultation or a high degree of certainty regarding which patients are candidates for thrombolytic therapy and, in particular, which patients are not candidates. The same study also assessed changes in the use of thrombolysis in spoke hospitals compared to the time before their inclusion in the telestroke network. They found an increase in the use of rt-PA in the spoke hospitals by a factor of 2-3 [97]. However, this increase has to be interpreted cautiously because the time window for thrombolytic therapy was extended during the study from 3 to 4.5 hours [97].

Within the California-based STRoKE DOC trial (Stroke Team Remote Evaluation Using a Digital Observation Camera) the efficacy of stroke telemedicine decision making was prospectively assessed [99]. Within four spoke hospitals, 222 patients with a suspected stroke were randomly assigned to telemedicine or telephone consultation. This study found that telemedicine consultations resulted in significantly more accurate decision making (98% correct decisions) compared with telephone consultations (82% correct decisions). The 90

days functional outcomes (mRS) did not differ between the groups. No difference was found in the post-thrombolytic intracerebral hemorrhage rate. Also, mortality did not differ between the groups (with and without adjusting for baseline NIHSS score severity) [99]. The lack of differences in the functional outcomes is mainly due to the low number of included patients, such that the study was underpowered with respect to the expected effect. A further study also compared telemedicine with telephone consultations using a prospective randomized design [100]. This study found 89% correct treatment decisions if telephone consultations were used and 85% correct if telemedicine was used. No differences in functional outcomes were found. However, the cited study included only 54 patients (27 in each group), and technical problems were reported for 74% of the cases in the telemedicine arm [100], which strongly limits the interpretability of the results of this study [100].

Some other studies did not investigate functional outcomes but instead evaluated more specific parameters related to the telemedicine intervention. These studies are important to identify the characteristics of telestroke networks that are associated with good performance in specific aspects of stroke therapy. In a retrospective study, it was found that participation in a telestroke program increased the rate of thrombolysis administration to patients by 55% [101]. During one year of active telestroke work, the proportion of patients transferred to a primary stroke center after teleconsultation decreased from 44% to 19% [101], indicating a steep learning curve for the spoke hospital in handling acute stroke patients.

In conclusion, there is strong evidence that telestroke networks improve the functional outcomes of patients in rural locations. This is mainly achieved by increased rates of thrombolysis administration to patients with a decreased onset-to-treatment time.

COST-EFFECTIVENESS AND REIMBURSEMENT MODELS

Stroke is the leading cause of disability in developed countries, with costs of more than \$40 billion annually in the USA [26]. The financial systems underlying health care differ widely between countries. Most data are available from telestroke networks in the USA. The financial models for the reimbursement of telestroke networks might differ to some degree in different countries. In some countries, the telestroke service is paid for by the state health insurance (e.g., Finland). However, in most health care systems, telemedical consultation with a specialist results in no or minimal additional reimbursement by health insurances. Even in cases where an additional coverage is paid, these payments are described as inadequate [3]. Therefore, the reimbursement model requires the use of other sources to cover costs.

Macroeconomic Cost-Effectiveness of Telestroke Networks

With respect to the costs of initiating and maintaining a telestroke network, the question arises of whether these costs are worthwhile for the additional health benefits gained. The second important question is whether telestroke networks can deliver a positive financial outcome for the health system by improving outcomes and reducing long-term nursing expenses.

Analyses of the cost-effectiveness of telestroke networks are available only for a few countries. A US study developed a model to compare the costs and effectiveness of stroke care with and without a telestroke network over a 5-year time horizon [28]. The results suggested an increased rate of thrombolysis for patients treated within the telestroke network, leading to an increased rate of patients who were discharged home without requiring additional care. The cost analysis found a cost saving of ~\$100 000 for each spoke hospital, while the hub hospital had additional costs of ~\$400 000. Due to the size of the study network (seven spokes), this analysis resulted in cost savings overall. However, the authors also demonstrated the sensitivity of cost savings to the number of spokes within a telestroke network due to the fixed maintenance expenses of the hub [28].

A similar study was based on a Danish health economic model of thrombolysis treatment in a telestroke network [27]. The results suggested that the macroeconomic costs were balanced by savings in care and rehabilitation after two years and that the cost-effectiveness improved over longer time scales. However, this study also showed that the budgetary impact depends on the number of spokes and their capacity as well as on the organizational conditions at the spoke hospitals [27].

All of these studies of the cost-effectiveness of telestroke assumed that the financial effects are solely due to an increased use of rt-PA. Other potential causes for cost savings associated with telestroke consultations were not taken into account. A more general analysis was performed within the TEMPiS system. The costs of inpatient and outpatient care in a typical hospital population were investigated over 30 months. All of the patients suffered from a stroke but did not necessarily receive rt-PA. This study concluded that the additional costs of telestroke consultation were fully compensated by the cost savings in outpatient care [102].

Overall, the available studies that have analyzed the cost-effectiveness of telestroke concluded that from a long-term perspective, telestroke seems cost-effective compared with usual care, mostly because telestroke costs are upfront and the benefits of better stroke care are lifelong [27, 28, 30, 102-104].

Reimbursement Models of Hub Hospitals

Telestroke service incurs additional costs for the providing hospital. First of all, there are the initial equipment costs, which mainly depend on the level of service offered. During operation, personnel costs are an important component. Most hubs and spokes have access to dedicated technical support during the consultation process, which also contributes to the operating costs.

Reimbursement models vary widely between health care systems. In some countries like Finland, telestroke service is directly paid for by the state or health insurance companies. However, these cases are the minority. In most countries, it is the responsibility of the hub hospital as the service provider to reimburse the expenses. This is mainly done by on-call pay for telestroke consultations from the spoke hospital to the hub. Another model is the sharing of additional income for the spoke hospital that is caused by the telestroke network. This model is applicable in countries where the use of rt-PA and/or the initial attendance by a neurologist generates additional income for the spoke hospital. Some telestroke networks have formal agreements about the partition of this additional income. This model has the

advantage of a win-win situation for both hospitals. However, the downside of this reimbursement model is that telestroke consultations with diagnoses other than stroke will generate work instead of income for the hub hospital. In particular, in this model, the threshold for telestroke calls by spoke hospitals is very low, and the average reimbursement per call is low for the hub hospital.

Aside from direct reimbursements, a telestroke network binds the spoke hospitals more tightly to the hub hospitals. Patients who have to be shipped after a telemedicine consultation are mostly shipped to the hub hospital. The hub, however, can admit a patient only in case of free capacity. Eventually, this can lead to a decrease in free capacity and an increased degree of capacity utilization in the hub hospital, rendering the latter more cost efficient.

Reimbursement Models of Spoke Hospitals

In most cases, participation within a telestroke network does not cause expenses for the spoke hospital apart from the costs for technical equipment and telemedical maintenance costs. Depending on the contracts between hub and spoke hospital, telestroke consultations will be paid per call or alternatively, the additional income for the spoke hospital that is produced by the telestroke consultation is shared. In the second case, no reimbursement is necessary. In the first case, the additional income produced by the telestroke consultations has to compensate for the costs of the telestroke consultations. Some insurance companies in some US states reimburse spoke hospitals for telestroke consultations, but these payments were described as insufficient [3]. To compensate for the increased diagnostic and therapeutic effort, Medicare has created a higher-value diagnostic related group (DRG-559) for the use of rt-PA in acute stroke. However, the increased reimbursement is only paid if the patient remains in the hospital where the rt-PA was administered. In the case of a “drip and ship” case, neither the spoke nor the hub hospital receives that increased reimbursement. This system is particularly questionable in light of the recently published results from intervention studies, which demonstrated improved functional outcomes after rapid endovascular treatment for patients with an acute ischemic stroke with a proximal vessel occlusion [8-11].

As another example, in Germany, thrombolytic therapy produces additional income, similar to the DRG model in the US. Furthermore, German insurance companies pay additional reimbursements if the patient is treated within a “stroke unit” and is examined by a neurologist. An initial telestroke consultation is accepted by the insurance agencies similarly to neurological bedside examination.

Additionally, telestroke consultations enable the spoke hospital to deliver rt-PA onsite instead of transferring the patient to a specialized stroke center [40, 105, 106]. This motivates many rural hospitals to implement their own system of stroke care, moving from a “ship and drip” to a “drip and keep” model. This has led to a retention rate of 60-70% of patients at spoke hospitals, with significant cost savings [32, 103].

PROBLEMS AND LIMITATIONS IN TELESTROKE

Quality of Service

It has been demonstrated that the percentage of consultations that lead to rt-PA use vary widely [23, 94, 97, 99]. Also, within a single telestroke network, there are variable results on the percentage of rt-PA delivery in spoke hospitals [62]. The reason seems to be multifactorial. A recent study identified the presence of a stroke nurse coordinator at the spoke as an important factor for improved treatment of ischemic stroke with rt-PA [62]. However, it remains an open question whether this is solely a direct effect of the stroke nurse coordinator or whether the nurse coordinator is an expression of the commitment for acute stroke treatment that a spoke hospital is willing to do aiming to increase the quality of the telestroke network. This commitment could also add to this effect through a multifactorial influence.

Technical Problems

When telestroke networks were first being put into use, the lack of bandwidth caused often an insufficient video quality. Today, most video-conferencing systems offer high quality videos. However, depending on the organizational structure of the telestroke network, the stroke specialist is not always at the hub hospital and may have to perform his telestroke consultation from home. There can be a lack of bandwidth. However, in our experience, even if the video quality is reduced, this does not usually affect the ability to obtain an accurate NIHSS score.

Interestingly, a prospective study from 2010 found technical problems during the performance of telestroke in 74% of consultations [100]; these problems affected video, audio, the internet connection, image forwarding or multiples of these [100].

Non-Stroke-Telemedicine

Imagine the following situation: it is night at small rural hospital, and there is only one physician in his second year at the emergency department as a patient is brought by the paramedics with unclear neurological symptoms that cannot be interpreted as stroke. The physician knows that there is a very experienced neurologist only one call away who can examine the patient through the telestroke equipment. Why should he not call? In particular, if the contract with the hub does not involve a pay-by-call model and instead employs a profit-sharing model, there is an increased tendency to use the telestroke network for these cases as well. Indeed, it would be morally unacceptable to withhold this expertise from the patient. In our own experience, there is a massive trend toward using the telestroke network not only for stroke patients, but also for patients with stroke mimics and other neurological syndromes, and ideally, this should be considered a feature instead of a bug.

US-Specific Problems – Licensing and Accreditation

In the USA, the telestroke consultant must be licensed by the state and hold credentials at the local hospital. Today, there are no national or multistate licenses for telestroke that could reduce the burden on the stroke consultant to be licensed in multiple individual states if the telestroke network extends across state borders [107]. In Europe, there is no such thing as “state licensing” within countries. The telestroke consultants have to be licensed in every country. Currently, there is no Europe-wide licensing. However, this does not constitute a problem in this context due to the lack of telestroke networks across country borders.

PERSPECTIVES

In the last decade, telestroke has undergone rapid growth and is now advancing into the mainstream of acute stroke care. Telestroke has been shown to improve the functional outcomes of patients and is also cost-effective. However, telestroke networks are still locally organized, and there is mostly a lack of national and international standards for the technology, quality of care and organizational structure of telestroke networks. Today, the technological advancements of broadband networks enable even the smallest and most remote hospitals access to state-of-the art neurological stroke expertise. This opportunity is only limited by the will of participants and in some countries (particularly the USA), national and state regulations. Ultimately, telestroke will diminish geographical disparities in access to expert care, with the aim of ensuring that all patients with acute stroke receive optimal care. This aim also requires the political will to ensure that no hospital should treat acute stroke patients without neurological expertise. In this context, changes to reimbursement are also required that will provide incentives for stroke specialists to provide on-call cover.

Discarding the “Ship and Drip” Model

There should be general agreement that the “ship and drip” model is not state-of-the-art treatment for acute stroke patients. A hospital that is using this method should be integrated into an existing telestroke network. Every effort should be made to ensure that thrombolytic treatment can be provided by every hospital that sees patients with symptoms of an acute stroke. A “drip and ship” model could then be further extended to a “ship and keep” model where unproblematic stroke patients are treated, and the telestroke network can then be used for further directions.

Non-Stroke-Telemedicine

As stated above, the use of telestroke networks to evaluate non-stroke neurological cases should not be seen as misuse but as an important extension to the ability to bring expert neurological knowledge to rural locations. A recent retrospective study evaluated 352 teleconsultations with a non-stroke diagnosis [108]. It was found that the time required for a

teleconsultation for a non-stroke patient nearly doubled the time of stroke cases (26.5 minutes vs. 14.3 minutes). It was further found that diagnostic accuracy was not as exact in non-stroke cases compared to acute stroke cases [108]. However, from our own experience, it should be noted that a stroke is in most cases, one of the most recognizable neurological diseases. Furthermore, telestroke equipment was developed to evaluate acute stroke patients. Therefore, it is less feasible, however possible to use this equipment to investigate impaired oculomotor features or movement disorder symptoms, for example.

The E-Stroke Unit

Patients with acute stroke not only require specialized neurological attention during the hyperacute stage but also benefit from organized stroke care (“stroke unit”) during the following days [109, 110]. Most of the requirements of such a stroke unit can be provided by smaller hospitals (e.g., cardiopulmonary monitoring, speech and language therapy, and physiotherapy). However, specialist coverage of these patients by neurologists often remains the main challenge. Today, the question is whether repeated teleconsultations can compensate for the lack of an in-house stroke expert. Moreover, the idea of mobile telemedicine workstations has been discussed to enable the remote stroke expert to become virtually present at the patient’s bed to supervise the stroke care [34].

Chapter 32

IMAGING IN ACUTE STROKE

Mirco Cosottini* and Graziella Donatelli

Department of Translational Research and New Technologies in Medicine
and Surgery, University of Pisa, Pisa, Italy

ABSTRACT

Acute ischaemic stroke is one of the neurological urgencies. Intravenous thrombolytic therapy should be initiated within 4.5 hours from symptoms onset; unfortunately, many patients with acute stroke are admitted to hospital with an acute stroke with unknown time of onset or after the therapeutic window.

Nonenhanced CT is currently used to exclude contraindications to fibrinolytic therapy, and CT Angiography can show the presence of a thrombus within a large vessel. On the other hand, advanced imaging modalities, such as CT and MR perfusion, seem to be new promising tools in the pre-treatment assessment of patients as a surrogate of ischaemic penumbra. The research of radiological markers of ischaemic but savable tissue might change some criteria for patient selection for treatment. However, clinical trials performed over recent years have often shown conflicting results. This inconsistency was probably partially caused by different criteria adopted for patient selection, and by the use of different imaging modalities and technical parameters. Further randomized controlled studies are essential in order (i) to establish if perfusion-based criteria to select patients for treatment lead to a better outcome within and/or after 6 hours from symptoms onset; and (ii) to investigate if there are reliable radiological criteria to exclude patients that do not benefit from reperfusion.

INTRODUCTION

Acute ischaemic stroke can be treated if therapy is administered in the early phase of the disease. Intravenous thrombolysis with recombinant tissue plasminogen activator (rtPA) is the first-line therapy and should be initiated within 4.5 h from symptoms onset in order to obtain a good clinical outcome [1]. In selected patients, endovascular treatment represents an integrative option and allows a wider therapeutic time window (usually 6 hours in the anterior circulation and even more in the posterior circulation).

The treatment of ischaemic stroke is based on brain imaging to guarantee appropriate patient selection and to avoid complications [2]. The goals of neuroimaging are: (i) to exclude contraindications to reperfusion; (ii) to rule out differential diagnoses; (iii) to detect arterial occlusions; (iv) to evaluate the infarction core and ischaemic penumbra. Therefore, the role of imaging can be summarized in the “four P’s” [3] that include the assessment of Parenchyma, Pipes, Perfusion and Penumbra. Different imaging techniques are specifically adopted to achieve each aim: CT scan without contrast administration (NCCT) and conventional MRI with DWI are used to study the brain parenchyma; CTA or MRA are useful for vessel assessment; and CT Perfusion (CTP) or MR-PWI allow the evaluation of perfusion and the penumbra.

NONCONTRAST COMPUTED TOMOGRAPHY (NCCT)

NCCT is the mainstay of the acute stroke workflow based on its high level of evidence in the exclusion of intracranial haemorrhage and in the revealing of stroke mimics (Figure 1a-b) [4]. It has several advantages: it is fast, widely available and feasible.

A radiological contraindication to fibrinolytic therapy is the presence of large hypodense acute ischaemic changes in more than one-third of the middle cerebral artery (MCA) territory [5]. A quantitative method useful to select patients who are not suitable for revascularization is the Alberta Stroke Program Early CT Score (ASPECTS) [6]. According to this method, the MCA territory in each hemisphere is divided into 10 regions with an overall maximum score of 10 points. Then, for each region in which acute ischaemic CT signs are recognised, one point is subtracted from the maximum score. Patients with an ASPECTS below 7 are less likely to benefit from thrombolysis.

NCCT also provides early signs of ischaemic stroke but with limited sensitivity (31% at 3 hours and 82% at 6 hours) [7] and reliability [8], especially in the posterior fossa and for lacunar infarctions [9]. Furthermore, early signs of ischaemic stroke are subtle on NCCT and have a high intra- and inter-observer variability, but they are not a contraindication to fibrinolytic therapy [4]. They include the loss of gray-white junction differentiation, the sulcal effacement and the loss of delineation of the basal ganglia and the insular ribbon (Figure 1c). The hyperdense artery sign (or dot sign) is attributed to the presence of a thrombus within the lumen of a large vessel and it is detected in about 30% of thrombosed intracranial vessels [10].

Figure 1. NCCT allows the immediate detection of the hyperdensity of blood in haemorrhagic stroke (a) and reveals several stroke mimic conditions, e.g., a Todd's palsy after an epileptic seizure secondary to a small cavernous angioma of the right hippocampal formation (b). In (c) early signs of ischaemic stroke are shown: note the Sylvian fissure effacement and the loss of delineation of the insular ribbon in the right hemisphere.

MAGNETIC RESONANCE IMAGING (MRI)

There is evidence that MRI, as well as NCCT, can be used to rule out intracranial haemorrhages [11] and stroke mimics in patients that are candidates for fibrinolysis [4]. Furthermore, MRI has a higher sensitivity than NCCT in detecting ischaemic tissues and avoids exposure to ionizing radiation. Nevertheless, several constraints limit its use in patients with ischaemic stroke. The first limitation is the lack of availability of the MRI service on a 24/7 basis. Moreover, the management of the acute phase of stroke, respecting the MR compatibility, is often difficult and time consuming. A further limitation is related to the MR protocol for patients with stroke that has to be essential and rapid to compete with the CT-based protocol.

The most important MR sequence is Diffusion-weighted imaging (DWI) that detects areas of restricted water diffusion in the brain as a sign of cytotoxic oedema. The performance of DWI for this purpose is excellent, having high sensitivity (88-100%) and negative predictive value (96%) just a few minutes after the stroke onset [12], consistently outperforming conventional MR sequences and CT (Figure 2) [13]. In patients with stroke the area of restricted diffusion is considered as the ischaemic core [14], but reversible DWI lesions after stroke are reported, often with an embolic origin [15].

Figure 2. DWI is the most powerful method to reveal cerebral ischaemia. In the left of the image, DWI reveals an area of signal hyperintensity in the left frontal lobe corresponding to the cytotoxic oedema during the hyperacute phase of stroke, when CT scan (in the right side of the image) is still unremarkable.

Similar to NCCT, DWI is used to exclude patients at risk for haemorrhagic complications during fibrinolysis. Exclusion criteria are: (i) a large infarct with cytotoxic oedema that involves more than one-third of the MCA territory; (ii) an infarct volume larger than 70 ml; and (iii) an ASPECTS < 8.

The MR protocol in acute ischaemic stroke has to be implemented with MR techniques for vessel imaging (MRA) such as Time of flight (TOF). MRA is a flow-based technique and does not require injection of contrast medium, but it is prone to specific artefacts that tend to overestimate the stenosis. With respect to CT Angiography and mainly to DS Angiography, MR Angiography is able to detect proximal vessel occlusions but it is not sensitive in identifying occlusions of distal branches.

Fluid attenuated inversion recovery (FLAIR) sequences are usually included in the MR protocol for the patient with acute stroke. Signal hyperintensity in FLAIR images is detectable later than reduced diffusion in DWI [16]. In patients with undated or wake-up stroke, FLAIR images can be used to estimate the time from the ischaemia onset. Ischaemic lesions that are detectable in DWI but not in FLAIR images are probably dated within the therapeutic window of 4.5 hours and can be safely treated with reperfusion therapy [17]. Furthermore, patients with stroke of unknown time of onset and selected by means of DWI/FLAIR mismatch have a good clinical outcome after recanalization therapy [18].

In dedicated centres, the duration of MRI exams to assess patients with acute stroke is less than 15 minutes. Although this scan time does not significantly prolong the time to treatment, the use of CT is more appropriate and recommended for good clinical practice [19].

CT ANGIOGRAPHY (CTA)

CTA with multi-detector CT technology is an alternative to catheter angiography in the evaluation of intracranial and extracranial vasculature, providing information about the location and extent of the thrombus (Figure 3). CTA revealed higher sensitivity than MRA for both intracranial stenosis (98% versus 70%, $P < .001$) and occlusion (100% versus 87%, $P = .02$). Moreover, CTA had higher positive predictive value than MRA for both stenosis (93% versus 65%, $P < .001$) and occlusion (100% versus 59%, $P < .001$).

Figure 3. CTA of intracranial vessels reveals the occlusion of the upper branch of dichotomization of the right middle cerebral artery.

CTA is performed by means of an intravenous injection of iodinated contrast media; the scanning is timed with the injection and starts from the aortic arch up to the level of intracranial vasculature. CTA provides important information for the planning of the endovascular approach to thrombectomy due to its panoramic view, the ability to always depict the presence or absence of the intraluminal thrombus (the target of endovascular therapy) [21], and because it reveals anatomical variations or kinking of the vessels.

CTA gives no information about the dynamics of blood flow but it can provide an estimation of the collateral circles from leptomeningeal arteries. Collaterals play an important role in ischaemia because they increase the reperfusion rates and decrease both the infarct core size and the hemorrhagic conversion, thus improving clinical outcome with recanalization therapies [22]. An ischaemic area surrounded by poor collateral circles has a low probability of rescue. Collateral circles in the ischaemic hemisphere can be estimated by comparing the backfilling of the pial arteries beyond the blocked artery to the circle of the unaffected hemisphere [23]. The major drawback of CTA is that it is monophasic; for this reason, it is possible to mistime the contrast filling of blood vessels and this can cause an overestimation of the ischaemia. In order to avoid this disadvantage, it is possible to perform multiphase CTA. This is a relatively recent technique that obtains a series of time-resolved angiograms by injecting a single dose of iodinate contrast media. After the arterial acquisition

of the vasculature from skull base to vertex timed with a bolus trigger, a further three acquisitions are scheduled to obtain a late arterial, venous and late venous phases [24].

Until the recent review of the AHA guidelines for stroke management, a vascular study was recommended in patients with acute stroke after the therapeutic window for rtPA administration, especially if either intra-arterial thrombolysis or mechanical thrombectomy was contemplated for management [4]. With the affirmation of the endovascular thrombectomy, CTA became the second recommended imaging technique after NCCT, when selecting patients for endovascular therapy [25]. In fact, the new revised guidelines for stroke management state with high level of evidence that non-invasive intracranial imaging should be obtained as quickly as possible in patients with stroke [26].

MR PERFUSION

Perfusion techniques are advanced MR methods introduced to explore the physiopathology of stroke and to improve patient selection for treatment, in order to achieve a better outcome of treated patients and to reduce futile treatments.

Some different definitions of ischaemic penumbra have been proposed over the years. Basically, the penumbra is an ischaemic and functionally impaired brain tissue whose haematic flow is lower than the threshold of electrical failure and higher than the threshold of energy and ion pump failure [27]. The impaired tissue is still viable and might be saved if reperfused before it is irreversibly damaged and recruited into the infarct core [28]. The ischaemic penumbra is becoming a possible milestone in the workflow of patients with acute ischaemic stroke. All medical and interventional treatments aim to save as much brain tissue as possible and to obtain as better clinical outcome as possible. However, not all impaired tissue can be saved: in fact, unlike the ischaemic core, the functionality of ischaemic penumbra can be theoretically restored by means of vessel recanalization and tissue reperfusion. If this is true, the absence of ischaemic penumbra also immediately after symptom onset would make any therapy useless. On the contrary, the presence of ischaemic penumbra even beyond the accepted time window for reperfusion might be a criterion to select patients that could benefit from treatment also at later stages.

Unfortunately, this is not so easy to achieve in daily practice. The first problem concerns the definition of ischaemic penumbra: it is not a radiological definition but there is a need to discover its radiological counterpart. Description of penumbral tissue using imaging used to come from PET studies, whereas nowadays it is usually evaluated by using MRI and is supposed to be represented by the perfusion-diffusion mismatch, that is the difference between the volume of perfusion and diffusion impaired tissue. There is currently no agreement about the most reliable perfusion parameters or the best cut-off for the evaluation of the penumbral volume and the differentiation between ischaemic penumbra and benign oligoemia. As a consequence, different trials use different landmarks making comparison among studies hard.

Treatment of patients with acute ischaemic stroke aims to arrest the evolution of penumbral tissue into infarction, limiting the final infarct volume. Which are the patients that could benefit from the treatment and what are the best criteria for their enrolment? Is there a time limit after the symptoms onset for its safety and effectiveness? The possibility of using

radiological rather than temporal criteria to select patients for reperfusion might also allow to treat patients that today are excluded because of undated acute stroke.

In clinical practice and mainly in patients with acute stroke, cerebral perfusion can be measured adopting an MR technique that uses a non-diffusible exogenous tracer, named dynamic susceptibility contrast MR imaging (DSC-MRI). DSC-MRI is based on the local magnetic field inhomogeneities induced by the first passage of a contrast bolus of paramagnetic tracer through the cerebral capillary network. Echo-planar sequences allow the detection of rapid signal changes in the brain parenchyma with an adequate temporal resolution. Signal-time course data can be converted to relative tracer tissue concentration-time course data, and haemodynamic parameters such as cerebral blood volume, cerebral blood flow and mean transit time can be derived. Cerebral blood volume (CBV) refers to the blood volume fraction of the tissue and it is expressed in ml/100 g of tissue. Cerebral blood flow (CBF) is a measure of the blood volume delivered to the tissue in a certain time and it is expressed in ml/100 g of tissue per second. Mean transit time (MTT) is the time that a volume of tracer takes to traverse a specific volume of tissue and it is expressed in seconds. Absolute quantitation of cerebral blood flow has been attempted using DSC-MRI tracer kinetics analysis that measure arterial input to the brain. The arterial input function (AIF) is usually generated by manually placing a ROI at the level of the middle cerebral artery.

CBV maps are obtained by fitting the first pass response in the concentration time curves to a gamma variate and then integrating the fitted curve.

$$CBV = \frac{k_h}{\rho} \frac{\int C_{voi}(t)dt}{\int C_a(t)dt}$$

CBF calculation requires the deconvolution of a residual function from an arterial and tissue concentration-time data.

$$C_{voi}(t) = CBF \ C_{art}(t) \overset{\Delta}{\underset{\Delta}{\Delta}} R(t)$$

MTT maps are calculated based on the central volume principle, from the ratio of CBV to CBF.

$$MTT = \frac{CBV}{CBF}$$

Although the absolute perfusion measurement has been demonstrated to be in good agreement with accepted physiological flow rates, there are intrinsic difficulties in the quantitation because of the AIF measurement, bolus delay and dispersion.

Parameters directly derived from the tissue concentration-time curves are: (i) maximum peak concentration (MPC), that is the highest value of the tracer concentration after injection; (ii) area under peak (AUP), that is the intergral of the tissue concentration time curve; (iii) time to peak (TTP), that is the time from the tracer injection to the maximum concentration obtained; (iv) time to arrival (BAT), that is the time from the tracer injection to its arrival to

the tissue; and (v) full width at half maximum (FWHM), that is the width of the concentration-time curve at half of its maximum amplitude. These haemodynamic parameters are useful to obtain qualitative information in several pathologies but depend on many variables such as total body vascular volume, cardiac output, injection rate, injection dose, cannula size; therefore, they can not be directly compared either between different subjects or in the same subject in different times. Nonetheless, the reduction of their variability can be achieved using an internal standard of reference, such as the normal grey or white matter, and computing semi-quantitative or relative values.

With the affirmation of thrombolytic therapies, the need of a method to select patients that may benefit from systemic or intravascular treatment became a matter of urgency. Besides the area of reduced diffusion that identifies the infarct core, different PWI methods have been described to define the penumbra. The most employed method is the mismatch between altered DWI and PWI areas, but also thresholds of TTP and MTT are used to define the area with reduced perfusion (Figure 4). In the DEFUSE and EPITHET trials, the mismatch is defined as a 20% difference between PWI and DWI areas [29]. Furthermore, although DWI-PWI mismatch allows the identification of the brain tissue at risk of infarction, an ideal perfusion using non-time dependent parameters is not yet available.

Figure 4. MR evaluation of acute stroke. In conventional FLAIR image there are multiple areas of signal hyperintensity involving the cortical ribbon in the right frontal lobe, characterized by signal hyperintensity in DWI and reduced water diffusion in ADC map. These areas of cytotoxic oedema are considered to correspond to the irreversibly damaged tissue (infarct core) caused by the occlusion of the right middle cerebral artery visible at MRA. MR perfusion obtained with DSC techniques allows calculating CBF and MTT maps that reveal a large area of hypoperfusion extending beyond the infarct core. The mismatch between DWI and PWI areas is the ischaemic penumbra.

The potential usefulness of perfusion imaging in acute stroke includes: (i) the identification of the ischaemic core at increased risk of hemorrhage after thrombolysis; (ii) the identification of salvageable brain area with thrombolysis performed beyond the standard therapeutic window; and (iii) the management of patients with unknown stroke onset (i.e., wake-up stroke) [30].

Although widely available and used, the diagnostic and clinical usefulness of perfusion techniques have not been proven in controlled studies of adequate power [4].

CT PERFUSION (CTP)

CTP provides the detection of the ischaemic penumbra and the infarct core. Multidetector CT scanners, tracking the iodinated contrast media as an exogenous tracer through capillaries into veins, are able to display, for each pixel, a curve representing the contrast media concentration over time. Deconvolution analysis of arterial and venous concentration-time curves provides quantitation of CBV, CBF and MTT. [31] CBV is calculated from the area under the time-density curve; CBF is derived from the gradient of the wash-in of the time-density curve; MTT is derived from the central volume theorem according to the equation $MTT = CBV / CBF$ [32].

Figure 5. CTP evaluation of penumbra. Patient with acute onset of left hemiplegia and unremarkable NCCT (a). CTA (b) reveals thrombotic obstruction of the bifurcation of the right middle cerebral artery with good collaterals for the backfilling of distal vessels. CTP maps display a normal or slightly increased CBV (c) that corresponds to an increased MTT (d) in the middle cerebral artery territory and indicates penumbra with salvageable tissue if re-perfused. No clear ischemic core is identifiable. After recanalization, DWI (e) demonstrates only small foci of cytotoxic oedema within preserved middle cerebral artery territory. MRA (f) confirms the complete recanalization of the intracranial vessels.

CTP exploits the CBF-CBV mismatch to obtain the ratio between the infarct core and the penumbra [33]. Areas with increased values of CBV and MTT (or reduced CBF value) represent hypoperfused but viable tissue at risk of infarction (ischaemic penumbra), whereas areas with decreased CBV (or CBF) and prolonged MTT values represent irreversibly damaged tissue (infarct core) (Figure 5) [34]. If some studies state that the mismatch between CBV and MTT (or CBF) maps roughly represents the penumbra, other studies suggest the use of quantitative measurements of CBF as a predictor of the infarct core. A CBF reduction to 30%-50% with respect to the CBF of the contralateral hemisphere is considered a sign of irreversible tissue damage [35].

Further semi-quantitative parameters can be obtained from the analysis of the density curves, such as the TTP curve. By showing the time to reach the apex of the time-density curve, the TTP curve reflects the time that the contrast bolus takes to reach the tissue and, when increased, it is considered a sensitive marker of cerebral ischaemia.

Compared to MR perfusion techniques, CTP has a limited spatial coverage (but can be alleviated by the use of multi-detector CT scanners with more than 128 detectors) and is less sensitive in the detection of small lacunar lesions [36]. Nevertheless, CTP is more available, easy to manage in an acute setting, and together with NCCT and CTA, forms a continuum of diagnostic tools.

ROLE OF ADVANCED IMAGING IN STROKE: LIMITATIONS

A fast and accurate imaging to define perfusion and penumbra is desirable, and the capability to detect the potentially salvageable brain tissue in a single subject would be preferable to the mere exclusion of contra-indications provided by standard imaging. However, clinical trials which tested advanced imaging techniques for patient selection produced conflicting and inconclusive results [37-40]. In general, patients with perfusion mismatch treated with rtPA within 6 hours from symptoms onset had significantly attenuated infarct growth and higher reperfusion rate; however, mortality and clinical outcomes were not different compared to patients without mismatch [41]. A favourable penumbral pattern on neuroimaging does not identify patients who would benefit from endovascular therapy for acute ischaemic stroke if onset to treatment time has been too long [42].

To date, delayed thrombolysis in mismatch patients has not been confirmed to improve clinical outcome and, therefore, delayed treatment according to mismatch selection cannot be recommended. This conclusion is related to the definition of imaging-based mismatch which is still evolving [43] and is influenced by the physiopathology of mismatch and also by technical limitations. From a conceptual point of view, any attempt to determine the status of ischaemic and oligemic tissue with imaging is a snapshot in time [44] whereas the penumbra is a developing phenomenon and any perfusion threshold level is time dependent [45]. For this reason, a tissue is viable and salvageable at a certain threshold in a moment but it is no longer salvageable at the same threshold at a later time.

Beside these conceptual limitations, some technical constraints often make the results of different trials equivocal and the comparison among them hard. An attempt to clarify the terminology is on-going in the scientific community, aiming to reach common methods of acquisition and analysis of perfusion [46].

The parameters used in CTP and MR-PWI to describe the ischaemic core and the penumbra are different and do not always overlap [47]. In MR-PWI, the use of DWI for the identification of the ischaemic core has an important limitation: not all DWI lesions are irreversible [48] and they can disappear in a not negligible number of cases (24%) [49]. In both MR-PWI and CTP, different perfusion parameters (CBF, CBV, time to maximum, MTT, TTP) are combined to define ischaemic core and penumbra in ways which often differ among trials [50].

The most robust recognized method to estimate perfusion parameters is the deconvolution method [51, 52], even though assumptions underlying deconvolution algorithms have been questioned. In fact, it is stated that the proportion between signal change and tracer concentration in dynamic susceptibility contrast perfusion is maintained only for specific conditions [53]; moreover, the method adopted in clinical practice for the AIF selection influences blood flow measurements [54]. In Figure 6 we report an example of two different CBF maps depending on the method used to select the AIF (manually drawn with a ROI-based method proximally to the middle cerebral artery or automated selected using a home-made algorithm) [55]. Furthermore, perfusion parameters are affected by bolus delay and/or dispersion [56], which are related to the tracer-bolus geometry and concomitant neck vessel pathology. Automated methods to correct the bolus delay and the dispersion are described [57], but the use of these algorithms in software for clinical practice has not yet been implemented. Quantitative evaluations of perfusion parameters are also prone to error depending on different deconvolution algorithms [58] and software adopted for the analysis [59]. Therefore, the most reliable estimation of the size of the final infarct tissue can be assessed by computing CBF and MTT maps by means of a single value decomposition algorithm and a delay-insensitive software.

In order to improve the standardization and reproducibility of advanced imaging interpretation and to extend the use of this new technique also in clinical practice (rather than only in highly specialized academic centres), an automated, rapid and robust CTP-based mismatch selection method (RAPID) [60] has been developed and adopted for imaging-based selection in the EXTENDED IA trial [61].

The lack of standardized perfusion thresholds used to define penumbra and ischaemic core make the comparison among trials difficult. The use of several perfusion analysis methods and the multiple definitions of tissue at risk both help to explain the myriad of perfusion thresholds reported in the literature [62]. Recently, alternative perfusion methods encompassing specific thresholds to make predictions have been developed. These models use FLAIR, PWI or DWI images for the analysis of voxel intensity at onset with respect to the observed tissue fate, thus estimating the viable tissue at risk [63]. The voxel-wise analysis may use spatial clustering to increase the likelihood of voxels to be identified with penumbra or benign oligoemia. A further method to predict the tissue fate is to display the spatial gradient of a parameter instead of the parameter itself. Gradient of CBV seems to be able to distinguish between benign hyperemia and penumbra surrounding the ischaemic core [64].

Figure 6. The graph shows two different shape of AIF obtained with a manual (light line) or automated (dark line) detection. The use of two different AIFs to process the same PWI row data with the same deconvolution method generates different maps of CBF.

ROLE OF ADVANCED IMAGING IN STROKE: WHAT WE LEARN FROM THE TRIALS IN 2015

Until 2015, intravenous tissue-type plasminogen activator (rtPA) has been the only proven and accepted reperfusion therapy in acute ischaemic stroke [65]. Recent clinical trials (MR CLEAN¹, ESCAPE², EXTEND-IA³, SWIFT PRIME⁴ and REVASCAT⁵) proved the

¹ Multicenter Randomized Clinical Trial of Endovascular Treatment for Acute Ischaemic Stroke in the Netherlands.

² Endovascular Treatment for Small Core and Anterior Circulation Proximal Occlusion With Emphasis on Minimizing CT to Recanalization Times.

³ Extending the Time for Thrombolysis in Emergency Neurological Deficits_Intra-Arterial.

⁴ Solitaire With the Intention for Thrombectomy as Primary Endovascular Treatment.

⁵ Randomized Trial of Revascularization with Solitaire FR Device versus Best Medical Therapy in the Treatment of Acute Stroke Due to Anterior Circulation Large Vessel Occlusion Presenting within Eight Hours of Symptom Onset.

efficacy of adding endovascular therapy to intravenous rtPA because of the large vessel occlusion in the anterior circulation. In particular, endovascular therapy with mechanical thrombectomy was associated with better functional outcomes than standard medical care with rtPA [66]. The overarching philosophy and new approach of these recent studies is to select patients with small ischaemic core at baseline and adequate collateral circles or salvageable brain [67].

Until now neuroimaging, especially advanced techniques, has been used to extend the therapeutic window for including a larger number of patients with stroke that could benefit from reperfusion. In these new trials, imaging was used to identify intracranial thrombi and measure the extent of salvageable brain in patients with a higher a priori probability of good outcome because of small ischaemic lesions and good collaterals. Unlike previous negative studies, probably both the technical improvement in materials adopted for endovascular thrombectomy and improved patient selection could have driven this change in outcome [68].

The demonstration of thrombectomy as an effective treatment implies that intracranial vessels should be evaluated in the acute phase together with NCCT. Although NCCT combined with a high score of National Institutes of Health Stroke Scale (>10) would be sufficient to select the right patients for thrombectomy, the majority of neuroradiologists prefers a patient selection based on NCCT and CTA.

In MR CLEAN [69] and in REVASCAT [70], the use of CT ASPECTS <7 or DWI ASPECTS <6 to exclude patients with large baseline infarcts demonstrated benefits of endovascular treatment (OR 1.66 and 1.57). Furthermore, a better outcome after thrombectomy was proved by the ESCAPE study (OR 2.53) [21] that added CTA for patient selection. Minimal or no pial collateral vessels in more than 50% of the ischaemic anterior circulation, corresponding to ASPECTS of 5 or less in patients with anterior circulation obstruction, was documented to be a predictor of poor outcome.

Another important observation coming from the most recent trials is the impact of penumbra imaging. The EXTEND IA study selected the eligible patients by using CTP. By using dedicated not commercial CTP software, they defined the infarct core as the tissue where the relative CBF was $<30\%$ of that in normal tissue, and the penumbra as the surrounding tissue with a time to maximum (Tmax) delay of more than 6s. When patients were selected using MR evaluation of the penumbra, the DWI-PWI mismatch was defined as a mismatch ratio >1.2 , with absolute mismatch volume $>10\text{ml}$ and ischaemic core lesion volume $<70\text{ml}$. The use of perfusion data to select patients for thrombectomy led to 71% of functional independence (mRS=0-2), a greater result than that achieved in other trials which used NCCT and CTA.

The role of advanced neuroimaging techniques in selecting patients for thrombectomy is currently a matter of discussion. There are two main approaches to the problem of patient selection based on MR measurement of the perfusion; they can be summarized in “physiology is brain” and “time is brain.”

The imaging of penumbra is supposed to monitor the progression of the pathophysiological cascade during stroke, and its utility in selecting patients for reperfusion can be exploited in different phases of the pathologic process. Up until now, the physiological imaging has been evaluated at a later time or beyond the therapeutic window, when the benefit margin is smaller [71]. On the contrary, the EXTENDED IA and SWIFT PRIME trials evaluated the role of physiological imaging for patient selection within 6 hours, when a beneficial treatment is more likely. This different approach could explain the better outcome

than that described by other trials without physiological imaging. A recent observational study [72] supports the hypothesis that the perfusion imaging-based selection can improve the clinical outcome; in fact, patients with target mismatch and small infarct core had a better outcome than patients without mismatch. Perfusion within the current standard time window for thrombolysis can identify patients that more likely benefit from intravenous rtPA and, among these, a subgroup with “target mismatch” that can not be identified using clinical/NCCT criteria alone.

The second approach to the imaging based patient selection is pragmatic. It is based on imaging methods to exclude contraindication to treatment; furthermore, the imaging has to be performed as fast as possible because benefits from thrombolysis decrease over time. This pragmatic approach expects that NCCT and CTA findings (small core, proximal vessel occlusion, and good collateral vessels) are likely to lead to the same clinical decision as a CT perfusion-based paradigm. For this reason, it is not ethical to perform adjunctive diagnostic tests when a beneficial treatment is already available. The combination of NCCT and CTA is the most pragmatic approach used in the recent endovascular trials according to the Bayesian view [73] of the decision-making: an adjunctive diagnostic test in patient selection is justified if it changes the therapeutic decision. NCCT and CTA allow the exclusion of haemorrhage and the depiction of large vessel intraluminal thrombus, thus changing the therapeutic decision to re-perfuse; additional imaging techniques, such as CTP or MR perfusion, do not. This point of view criticizes the improved outcome of trials adopting a perfusion-based patient selection by contending that perfusion led to exclusion of several patients (25% in EXTEND IA) who probably would have been enrolled for thrombectomy if selected by using NCCT and CTA alone. Moreover, a re-evaluation of patients of MR CLEAN trial demonstrated that perfusion is useful and revealed that patients with mismatch >1.2 or ischaemic core <70 ml have a better outcome than other patients. However, perfusion can not exclude patients from treatment because patients with no mismatch or large ischaemic core also benefit from thrombectomy [69].

After the publication of successful endovascular treatment, NCCT has to be used to exclude intracranial hemorrhage and to estimate the infarct core size by means of ASPECTS. The vascular imaging with CTA or multiphase CTA is fundamental to assess vascular occlusion and obtain information on collateral flow.

CTP may not be necessary in the first 6 hours from onset where the efficacy of endovascular treatment is clearly proven but it can increase confidence in the assessment of the infarct core [74]. If we use more precise (specific) imaging such as perfusion, will we lose sensitivity and exclude patients who might benefit from treatment? This is the radiological question and it is still open [75].

ROLE OF ADVANCED IMAGING IN STROKE: FUTURE PERSPECTIVE

Imaging in acute stroke for patient selection has to be readily available in a stroke centre on a 24/7 basis. The best imaging measures for planning intravenous rtPA or endovascular thrombectomy are NCCT and CTA.

Advanced techniques for penumbra assessment could be introduced in an experimental protocol if they do not unduly delay the treatment. However, the volumes of infarct core and

ischaemic penumbra as predictors of clinical outcome are under judgment because of conflicting results coming from observational studies. The diagnostic and clinical utility of perfusion for patient selection has not been proven in controlled studies of adequate power [26]. Randomized controlled studies are necessary to introduce MR or CT perfusion in the clinical practice in order to establish if perfusion-based selection allows a better outcome within or beyond 6 hours and the exclusion of patients that do not benefit from reperfusion.

Advanced neuroimaging methods for patient selection can be applied with two different strategies. On one hand, they can be applied within the therapeutic window in order to select the subgroup of patients with the best response to therapy; in this case, it must be acknowledged that, probably, not all patients who may benefit from therapy would be treated (selective strategy). On the other hand, they can be applied beyond the therapeutic window in order to select a larger number of patients (inclusive strategy); in this case, probably more people would benefit from treatment but there would also be a greater numbers of futile recanalization. The planning of future studies has to consider these two strategies: to select less people for a better outcome at a single-subject level or to select more people for a better outcome at the population level.

According to the current guidelines, the time window for thrombolytic therapy (<4.5 h) is still a limitation for an extensive treatment of patients with stroke. About 15-25% of strokes manifest at wake-up [76] and a large number of patients with acute stroke are admitted to hospital with unknown time of onset of stroke or beyond the therapeutic window. Assuming that patients with a relatively small infarct core surrounded by a large penumbra, currently excluded from treatment because of the therapeutic window, might benefit from therapies, further studies will be necessary to assess the role of advanced neuroimaging techniques as markers of penumbra and in the selection of patients to recanalise (imaging-based selection rather than time-based selection). Pursuant to this, an imaging-based selection to extend the therapeutic window or enlarge the sample of patients who might benefit from late reperfusion could be based on the mismatch between FLAIR and DWI [17].

CONCLUSION

- 1) The application of multimodal imaging is limited by the Bayesian view of “time is brain” in the first six hours from stroke onset.
- 2) Multimodal imaging could have a role in the first six hours to select patients for intravenous rtPA administration.
- 3) Multimodal imaging could have a role in extending the therapeutic windowing after six hours or in wake-up strokes.
- 4) The evaluation of patient selection based on quantitative imaging is recommended in a randomized controlled trial.

Chapter 33

STROKE AND ATRIAL FIBRILLATION

E. Soldati, F. Menichetti and M. G. Bongiorni*

Second Cardiology Unit, Arrhythmology, Cardio-thoracic and Vascular Department,
University Hospital of Pisa, Pisa, Italy

ABSTRACT

Atrial Fibrillation (AF) is the most common cardiac arrhythmia. Although clinical presentation may strongly differ and symptoms may be absolutely absent in several patients, the presence of AF carries on a significant impact on morbidity and mortality. Patients suffering AF have a five-fold higher risk of ischaemic stroke. The risk of clinical events has therefore to be scored in AF patients, in presence of high risk anticoagulation therapy is mandatory.

The best approach to this problem should be the elimination of AF; unfortunately this goal cannot be achieved in a significant percentage of patients. Antiarrhythmic drugs are often ineffective or induce side effects. Catheter ablation is effective in a high percentage of patients in presence of paroxysmal AF, but this procedure doesn't currently reach satisfactory results in persistent and long lasting forms. Nevertheless in patients with high risk of stroke anticoagulation should be delivered even after successful ablation.

Currently alternative therapies may improve the results of Vitamin K Antagonist (VKA) drugs. Novel Oral AntiCoagulants (NOACs) may provide a superior effectiveness and safety in comparison to VKAs. In addition, in patients with contraindications to anticoagulation or high risk of bleeding, the percutaneous occlusion of the Left Atrial Appendage may be an effective solution.

Keywords atrial fibrillation, stroke, anticoagulation, left atrial appendage closure, catheter ablation

INTRODUCTION

Atrial Fibrillation (AF) is the most common cardiac arrhythmia [1]. In the western countries it is the most common cardiological cause of access to the Emergency Care and hospitalization [2].

Fibrillation means that the electrical activity of the atrial myocytes is completely uncoordinated, due to chaotic depolarizations where wavefronts move into the atria. Since the control and coordination of the sinus node is lacking, multiple impulses reach the atrio-ventricular node, thus inducing ventricular beats with irregular intervals and, usually, high rate.

The prevalence of AF in the overall population is not negligible. The incidence of AF episodes rises accordingly with the age and the arrhythmia is common in the elderly, particularly in presence of heart disease. Valvular diseases (mainly mitral valve pathology), heart failure and hypertensive cardiomyopathy significantly increase the risk of AF. Nevertheless AF may occur even in young people, in absence of any underlying heart disease. In the age decades up to 40 years AF is very uncommon; the incidence rises in the decades 40 to 60 years and in people aged over 70 years the prevalence of AF is estimated to be as high as 12% and rise over 20% in people aged more than 80 years. According with the improvement of life expectancy over time, the number of patients with AF in the overall population is getting greater and greater. In the USA the prevalence of AF in 2010 was estimated to range between 2.7 to 6.1 millions of people and is expected to rise up to 10 million in 2050 [3].

From a clinical point of view the impact of AF may range from absolutely asymptomatic to a very challenging condition. The most common symptom is palpitations due to the increase in heart rate and to the irregular heartbeats. Dyspnoea, dizziness and fatigue are common. The hemodynamic impact of AF is related to the underlying heart disease: usually well tolerated in normal hearts, it may precipitate heart failure and shock in patients with very depressed cardiac function. On the other hand many patients suffer of paroxysmal or persistent episodes of AF in absence of any symptom. It was observed that at the time of the diagnosis about 1 out of 3 patients affected by AF are absolutely asymptomatic and underwent medical examination for reasons not related to AF.

AF is classified as paroxysmal when any episode terminate spontaneously in less than 7 days, persistent when last longer or require a medical intervention to be terminated and permanent when it is impossible to restore the sinus rhythm or the attempt is judged to be useless due to the early recurrence of the arrhythmia.

A single AF episode or 2 may occur in healthy people during lifetime, usually in particular situations (overstress, alcohol or drug abuse, fever). The case of recurrent episodes implies that a mechanism inducing the arrhythmia is present and usually AF episodes are likely to increase over time. The time course of the disease usually shows the progressive transformation of paroxysmal AF forms into persistent and permanent ones. This mechanism is related to the possible progression of the underlying disease as well as the facilitating effect on AF due to the AF itself. Increasing burdens of AF were found to modify atrial refractoriness (facilitating the initiation and propagation of fibrillatory wavelets), to induce the prevalence of fibrous tissue into the atrial wall (increasing dyshomogeneity and decreasing mechanical compliance) and finally inducing a dilatation of the atrial size.

Experimental data clearly demonstrated that AF begets AF. Once the disease has induced such modifications in the atrial substrate, the clinical presentation usually progresses from paroxysmal to permanent.

CLINICAL IMPACT OF ATRIAL FIBRILLATION

Since the acute risk of AF is usually low and chronic arrhythmia may not significantly affect quality of life in most patients, in the past years AF was considered to be harmless. Most of the attention was addressed to the relief of symptoms, mainly by means of the control of cardiac rate and patients were usually reassured about the consequences of the arrhythmia.

Further data demonstrated that AF significantly impact on the outcome.

The presence of AF was estimated to three-fold increase the risk of symptomatic heart failure. Observational data report that in people with depressed cardiac function the presence of AF doubles the risk of major events and hospitalizations and significantly worsens the outcome.

In most of the longitudinal studies the presence of AF was found to double overall mortality. These data may reflect the higher prevalence of AF in patients affected by structural heart disease, nevertheless the presence of the arrhythmia was found to carry out significant morbidity and mortality.

Finally, AF was reported to increase the risk of clinical strokes as high as 5-fold, with a steep increase in percentage of strokes attributed to AF from 1.5% at ages 50 to 59 to 23.5% at ages 80 to 89 [4] Importantly, the clinical course of ischemic stroke associated with AF is often more severe than for strokes of other causes, further emphasizing the need for stroke prevention [5].

In addition, even in absence of clinically relevant episodes, a significant burden of AF episodes was demonstrated to induce asymptomatic strokes (as detected by TC or MRI scans) and may be responsible of dementia.

Many of the patients referred to the Stroke Units suffer of AF, often undertreated and in many cases underdiagnosed. It is estimated that at least 15% of the overall number of clinical strokes is related to AF. The neurological adverse events affect mortality and morbidity, and heavily impact on individual and social costs due to possible disabling outcome.

The relation between AF and ischaemic stroke was supposed to be related to arrhythmic episodes and to be time dependent. Since during AF the atrial wall is lacking of coordinated contraction, atrial systoles are missing. The velocity of blood flow into the atrial chambers is consequently reduced, peripheral portions as appendages or pouches into the walls may provide further reduction of flow thus leading to the formation of clots and thrombi that may in turn embolize, with significant clinical consequences when embolization occurs in the systemic circulation. The longer the duration of the arrhythmia the higher is the risk of embolization; conventionally, episodes lasting more than 48 hours are considered to be significantly risky.

The risk of stroke secondary to either paroxysmal or permanent AF is the same and, from the perspective of thromboprophylaxis, should be treated in the same manner [6]. This condition implies the need of anticoagulation therapy in order to reduce stroke events to the level of controls.

Table 1. CHA₂DS₂-VASc scoring system

	<i>Risk factor</i>	<i>Points</i>
C	Congestive heart failure	1
H	Hypertension	1
A2	Age $\geq$ 75 years	2
D	Diabetes mellitus	1
S2	History of stroke or transient ischemic attack or thromboembolism	2
V	History of vascular disease, either coronary or peripheral	1
A	Age 65-74 years	1
Sc	Sex category: Female	1

Many concomitant factors affect the risk of stroke in AF patients. The risk was proved to increase in the elderly, female gender is another risk factor. Congestive heart failure, hypertension and other systemic diseases such as diabetes and renal failure increase the risk of clinical strokes. All these factors have been included into score systems (CHADS₂, CHA₂DS₂-VASc) in order to carefully stratify the risk in individual patients and address the anticoagulation therapy [7]. Until recently, the CHADS₂ score [8] was the most commonly used, but it has been superseded by the CHA₂DS₂-VASc score [9]. The point system for this scoring system is shown in Table 1.

In contrast with CHADS₂, this updated system assigns 2 points for age over 75 years and accounts for stroke risk in the relatively younger group of patients (age 65–75) and in females, neither of whom were included in CHADS₂. The CHA₂DS₂-VASc score ranges between 0 and 9 with a respective estimated stroke risk of 0 to 15.2% per year. Note that for females who are younger than 65 years, no points are given for sex. The major advantage of the CHA₂DS₂-VASc score over the CHADS₂ score is that it is more accurate for lower-risk categories. It has been adopted in most of the recent guidelines that address stroke risk in AF.

Many concerns have been recently raised about most of these issues. First of all, in patients where AF is not permanent, embolization was supposed to be mainly related to sinus rhythm restoration. The recurrence of atrial contraction may mechanically displace thrombi from their sites into the appendages or adhesions to the endocardial walls. When embolization occurred later after an episode, the stunning of atrial contraction was identified as the cause of the late clinical event. Recent observations do not longer support this aetiology of clinical strokes. Data of cardiac monitoring provided by implanted Devices form rhythm management and implantable Loop Recorders demonstrated that a clear relation between AF and stroke episodes cannot be identified. Time relation between AF and stroke is absolutely variable and AF duration was not found to linearly correlate with the stroke risk. In addition in high risk patients (CHA₂DS₂-VASc score >4) stroke may occur even in absence of AF episodes.

According to these observations currently AF is no longer considered as a strict risk factor, but is going to be identified as a risk marker, to be combined with other concomitant factors that impact on the patient's risk profile.

The CHA₂DS₂-VASc score has been confirmed as a more effective method of stratifying stroke risk in patients with AF, compared to CHADS₂, and is able to identify truly low-risk patients who would not benefit from anticoagulation [10].

Current indications to anticoagulation therapy recommend to treat patients with high risk score even when AF is suppressed by specific therapy.

THERAPEUTICAL ISSUES

The overwhelming risk of stroke in AF patients, particularly when concomitant risk factors and morbidities are present, implies that any therapeutic option has to be used to reduce clinical events.

Mainstay of the therapy is stroke risk prevention and rhythm control.

The first step of this strategy is based on the diagnosis of AF.

As before mentioned many episodes of AF may be absolutely asymptomatic. Symptoms may be different in individual patients and may vary over time in each patient. Even in patients with typical symptoms during the arrhythmia, the incidence of asymptomatic may be as high as 50% of the true AF burden. Data from registries report that about in 30% of the patients AF is diagnosed in absence of symptoms; when episodes are frequent or persistent a significant percentage of the patients cannot adequately recognize the presence of AF, even if they were symptomatic in the past.

Actually, underdiagnosed AF, mainly in paroxysmal form, is very common.

In relation to the association with ischemic stroke, it is interesting to underline that AF may not be identified as the direct cause of the episode since a wide percentage of the patients have no longer AF during the hospitalization. History of palpitations may be not present or unreliable and even conventional monitoring may not identify the presence of paroxysmal episodes. Any effort in order to identify the presence of AF in this population should be recommended; currently the use of implantable Loop Recorder was found very effective and helpful.

ANTICOAGULATION THERAPY

The prevention of stroke is the mainstay of the treatment, either in case of acute episodes or in the follow-up of AF patients.

The use of anticoagulant therapy may prevent the increased stroke risk in AF patients. Guidelines clearly indicate the overwhelming importance of anticoagulant therapy in such patients. Nevertheless all the data from clinical practice report that usually about one half of the patients with indications to anticoagulation are not treated.

On the other hand the benefit of anticoagulation is actually faced by an increased the risk of bleeding induced by the therapy. A careful evaluation of the risk/benefit ratio is required in any individual patient.

In absence of chronic therapy, acute episodes are considered to raise no significant risk of embolism in the first 48 hours since the occurrence. It is then critical to reliably determine the time of onset of any episode. If it is impossible or when AF lasts longer than 48 hours, anticoagulation (mainly using heparin) is mandatory. In case of unstable clinical conditions, when urgent restoration of sinus rhythm is judged to be necessary, there is a general agreement about the use of Transoesophageal Echocardiography in order to assess the possible presence of thrombi into the Left Atrial Appendage (LAA).

In AF patients the risk is estimated according to the score. In male patients with a CHA₂DS₂VASc score of 0 and in most patients with a score of 1, the stroke risk is less than 1% per year, and it not significantly differs from controls. These patients are not likely to

benefit from anticoagulant therapy. They are usually approached on a case-by-case basis with careful assessment of bleeding risk and discussion of risks and benefits of anticoagulant strategies [11].

A 2% per year cut-off is usually used to identify high-risk patients in whom the risk of stroke significantly outweighs the risk of bleeding on anticoagulants. In general, patients with a CHA₂DS₂-VASc score equal to or greater than 2 have a greater than 2% stroke risk per year and are most likely to benefit from antithrombotic therapies [12].

The benefit of anticoagulant therapy is unfortunately balanced by the risk of bleeding induced by drugs. Even the risk of bleeding is assessed according to the clinical profile of the patients, taking in account comorbidities, which can increase the risk and lifestyle. A clinical score is currently used in order to stratify the risk profile in individual patients, the HAS-BLED score (Table 2). Interestingly, most of the parameters used in score systems evaluating the risk of stroke are included in the score system evaluating the bleeding risk; finally patients who are more likely to benefit by anticoagulation are more likely to have side effects during therapy.

Generally, a HAS-BLED score of 3 or greater indicates increased 1-year risk of intracranial bleed, bleeding requiring hospitalization, drop in hemoglobin of at least 2 g/dL, or need for transfusion.

One problem with the bleeding risk scores is that they were derived from studies that included bleeding events of different severity. Most bleeding events do not lead to death or severe disability with the exception of intracranial bleeding, which is, therefore, the primary concern when assessing bleeding risk.

The estimated bleeding risk with anticoagulant therapy ranges from 0.2% to 0.4% per year but could be much higher in patients with prior severe bleeding, intracranial hemorrhage, thrombocytopenia, coagulopathies, recent surgery, or ongoing bleeding, aortic dissection, malignant hypertension, and in those receiving a combination of anticoagulant and antiplatelet agents (i.e., patients affected by Ischemic Heart Disease, recipient of coronary stents).

Once the decision to initiate anticoagulation has been made, assessment of whether the patient is a suitable candidate for warfarin therapy is required.

Warfarin has been used for decades for stroke prevention. It remains the only acceptable anticoagulant in patients with valvular AF. Multiple randomized clinical trials have assessed the efficacy of warfarin for stroke prevention in patients with nonvalvular AF [13]. These trials demonstrated that warfarin significantly reduces stroke risk, stroke severity, and 30-day mortality compared with no anticoagulant therapy [14]. The net clinical benefit of warfarin increases the longer the patient remains within the therapeutic range achieving net benefit over antiplatelet therapy when the TTR is above 65–70%, with an optimal TTR defined as >70% in a recent European consensus document [15, 16].

Difficulty in achieving adequate control of anticoagulation with warfarin has been cited as a common barrier to its use [18]. A poor control of anticoagulation is correlated with increased bleeding and thromboembolic risk [19]. Indeed, it has been shown that when TTR falls below 50%, stroke outcomes are worse than if the patient remained untreated [20], and bleeding risk is higher [21].

The importance of achieving satisfactory control of anticoagulation rapidly after starting warfarin has been illustrated by studies examining the incidence of stroke in the first month

after warfarin initiation; this period was associated with a 71% increased relative risk of stroke, presumed to be due to the hypercoagulable state.

Another limitation with the medication is the dietary restriction on intake of vitamin K-rich green vegetables, which are emphasized as healthy food choices especially in patients with heart disease. Higher warfarin doses are required in patients who consume greens and salads. It is important that patients be consistent in their intake of vitamin K-rich foods to avoid labile INRs, a difficult task for most patients.

Finally, there are several drugs that might interact with warfarin and potentially interfere with its safety or efficacy. These drugs include amiodarone, statins including simvastatin and rosuvastatin (not atorvastatin or pravastatin), fibrates (fenofibrate, gemfibrozil), antibiotics (sulfamethoxazole/ trimethoprim, metronidazole), and azole antifungals (fluconazole, miconazole, voriconazole). The use of drugs that induce the cytochrome P450 enzyme CYP2C9, such as rifampin, decrease warfarin effectiveness by reducing INR values. Other non-CYP2C9-dependent drug interactions exist as well.

ASPIRIN MONOTHERAPY OR IN COMBINATION WITH OTHER AGENTS

Aspirin monotherapy or aspirin plus clopidogrel both increase the risk of bleeding without appreciable benefit, and, as such, their use for stroke prevention in patients with AF is not well supported. The combination of aspirin plus low-dose warfarin was assessed in the SPAF-III trial [22] that randomized AF patients at stroke risk to either aspirin plus low-dose warfarin or to dose-adjusted warfarin to target a therapeutic INR. In this trial, patients on aspirin plus low-dose warfarin had significantly higher morbidity and mortality than patients who took adjusted-dose warfarin alone. Thus, the combination of low-dose warfarin plus aspirin should not be used for stroke prevention in AF.

In contrast, the combination of aspirin plus full anticoagulation with warfarin has not been well studied. Limited post-hoc data from the SPORTIF trials suggest, however, that this combination does not reduce the risk of stroke or thromboembolism more than warfarin alone [23].

Table 2. The HASBLED score

	<i>Risk factor</i>	<i>Points</i>
H	Hypertension	1
A	Abnormal renal and liver function	1 or 2
S	Stroke	1
B	Bleeding	1
L	Labile INRs	1
E	Elderly (e.g., age >65 years)	1
D	Drugs or alcohol (1 point each)	1 or 2

NEW ORAL ANTICOAGULANT DRUGS

Anticoagulant options have increased substantially in the past few years with the introduction of Novel Oral AntiCoagulants (NOACs), including the direct thrombin-inhibitor dabigatran and the factor Xa inhibitors rivaroxaban, apixaban, and edoxaban (Figure 1).

A limitation with these agents (versus warfarin) is that patients are not therapeutically anticoagulated when they miss a dose, whereas missing a single dose of warfarin may not have the same effect.

Dabigatran. The value of dabigatran for prevention of stroke or thromboembolism in AF was tested in the RE-LY trial (Randomized Evaluation of Long-Term Anticoagulation Therapy) [24]. In this trial, 113 patients with AF at high risk for stroke were randomized to dabigatran (110 mg or 150 mg twice daily) or adjusted-dose warfarin (INR target 2.0–3.0). By intention-to-treat analysis, dabigatran 150 mg was superior to warfarin for stroke prevention. Importantly, the risk of intracranial or life-threatening bleeding was significantly lower for both dabigatran doses compared with warfarin. Of note, gastrointestinal bleeding was more common with dabigatran 150 mg than warfarin; rates were similar for dabigatran 110 mg versus warfarin.

Rivaroxaban. This factor-Xa inhibitor was assessed in ROCKET-AF (Rivaroxaban Once-daily oral direct factor Xa inhibition Compared with vitamin K antagonism for prevention of stroke and Embolism Trial in Atrial Fibrillation) [25]. In this trial, 14,264 patients with AF and at risk for stroke were randomized to rivaroxaban (20 mg once daily) or warfarin (INR target 2.5). In the warfarin arm, INR was in the therapeutic range only 55% of the time. Results showed rivaroxaban was not inferior, but not superior, to warfarin for the prevention of stroke or systemic thromboembolism, the primary end points. From a safety standpoint, the overall bleeding rates were similar in the treatment arms with less life-threatening (fatal or intracranial) hemorrhage events with rivaroxaban.

Apixaban. This factor-Xa inhibitor was tested for stroke prevention in AF in two separate clinical trials [26, 27]. In the AVERROES trial (Apixaban Versus Acetylsalicylic Acid to Prevent Strokes) [26], 599 patients with AF deemed “unsuitable” for warfarin were randomized to apixaban (5 mg twice daily) or aspirin (81–324 mg daily). The trial was terminated early due to superiority of apixaban in achieving the primary end point: occurrence of stroke or systemic embolism. Importantly, the risk of major bleeding appeared to be similar with apixaban versus aspirin.

The ARISTOTLE (Apixaban for Reduction in Stroke and Other Thromboembolic Events in Atrial Fibrillation) trial [27] randomized 18,201 patients with AF and at least one additional risk factor for stroke to either apixaban 5 mg or warfarin (target INR 2.0–3.0). In this trial, apixaban was superior to warfarin for the prevention of stroke or systemic embolism, the primary efficacy end point. There also appeared to be a mortality benefit with apixaban versus warfarin. Importantly, the risk of major and intracranial bleeding, the primary safety outcomes, occurred at lower rates in the apixaban group.

All three of these oral anticoagulants require dose adjustment in patients with renal insufficiency and are contraindicated in patients with end-stage renal failure. They are not indicated in patients with valvular heart disease or a mechanical heart valves.

Figure 1. Mechanism and site of action of NOACs.

NON PHARMACOLOGICAL INTERVENTIONS

It is estimated that more than 90% of the thrombi rising into the left atrium form into the appendage. Non pharmacologic interventions have been developed to block the LAA to reduce the risk of stroke. These are especially valuable options for patients who are not candidates for chronic anticoagulation. In patients undergoing cardiac surgery [28], ligation to close the LAA has become a standard practice. Exclusion of the LAA cavity from the atrium can be achieved with devices that are positioned through an epicardial approach; however a thoracotomy approach is required. The introduction of less invasive catheter-based interventions to occlude the LAA has provided additional options.

Since the appendage is connected to the atrium by an orifice and (usually) a neck, the occlusion of the connection may result in total exclusion of blood flow from the appendage. Percutaneously positioning an occluding device in the appendage may obviate the need for sternotomy and cardiopulmonary bypass and is an attractive alternative to chronic anticoagulation with VKAs or NOACs in reducing stroke risk in non valvular AF.

LAA closure is an intervention of increasing interest, in particular for patients with either contraindications to anticoagulation therapy, embolic events while receiving anticoagulation therapy, or intolerance to anticoagulants.

Published trials demonstrate high overall success rates with favorable safety profiles compared with VKAs. Several device-related aspects still limit this approach, such as the high rate of incomplete LAA closure reported at long-term follow-up with transesophageal echocardiography and the occurrence of device embolization and migration.

Watchman device. The Watchman implant, a closure device that blocks the LAA, was recently approved by the US Food and Drug Administration (FDA) for stroke prevention in patients with non valvular AF who are at increased risk for stroke based on a CHA₂DS₂-VASc score of 2 or greater; candidates also must have an appropriate rationale for non pharmacologic therapy. The expandable-cage device is surgically delivered into the LAA, which subsequently endothelializes and isolates the LAA. Therapeutic warfarin is required for a minimum of 45 days after implant followed by aspirin and clopidogrel for 6 months and then aspirin alone.

This device was initially tested in the PROTECT AF (Watchman Left Atrial Appendage System for Embolic PROTECTION in Patients with Atrial Fibrillation) trial, a non inferiority

trial that randomized patients to either device implant or warfarin [29]. Device implant was successful in 91% of patients in whom it was attempted. Overall, the study showed non inferiority of the device to warfarin in terms of the primary efficacy standpoint, which included stroke, systemic embolism, and cardiovascular death; however, this came at the expense of higher incidence of procedure-related complications, which seemed to be dependent on a learning curve with the device.

In the PREVAIL (Evaluation of the Watchman LAA Closure Device in Patients with Atrial Fibrillation Versus Long-Term Warfarin Therapy) trial [30], although non inferiority was not achieved, the event rates were low and the safety of the procedure was much improved. This was also demonstrated in registry data, which showed improved safety with device implantation with increased operator experience.

Of note, both of these trials included only patients who were eligible for warfarin. Another nonrandomized study assessed the use of this device in patients with a contraindication to long-term anticoagulation. Results showed a very low incidence of stroke, which was lower than CHADS₂-matched controls taking either aspirin or clopidogrel [31].

Amplatzer Occluder. This device is similar to the system used to percutaneously occlude the Patent Foramen Ovale. It consists of two leaflets, connected by a shaft. When the device is deployed any leaflet approach to the edge of the ostium of the appendage, thus occluding the cavity itself. The design of this occluder may be helpful in presence of LAAs with limited longitudinal length, preventing the use of longer devices such as Watchman.

Data about the clinical use of the device are limited and most of them are provided by registries, thus clinical evidence of the results in a long term follow up is currently poor.

Lariat system. The Lariat system is another percutaneous system for occlusion of the LAA. This device, which requires both atrial transseptal and epicardial access, ligates the appendage from the pericardial space. While some small studies have shown it safe and efficacious in patients with AF who cannot take anticoagulation [32], other reports have not been as encouraging [33]. The device has been approved by the FDA for “soft tissue approximation”; it is not approved for stroke prevention.

Future refinements of LAA occlusion technology are expected to improve the feasibility of the procedure. The device design and coating should aim to overcome the limitations of incomplete LAA orifice sealing and device dislodgement. In contrast, acute procedural complications have been shown to be influenced by a learning curve, and operator experience deeply affects outcomes of the procedure [34]. Due to the skills and experience in transeptal puncture and navigation into the left atrium, Interventional Arrhythmologist are considered the recommended operators for this procedure.

One caveat is that there is a residual risk of stroke after undergoing LAA occlusion because the same risk factors for stroke in AF contribute to stroke from atherothrombosis and atheroembolism; also, thrombi can form in the body of the left atrium.

RHYTHM CONTROL: DRUGS AND RADIOFREQUENCY CATHETER ABLATION

In order to solve this clinical problem the most direct and effective approach could be to stop and (more) to prevent AF.

In the past the only possible approach was the use of AntiArrhythmic (AA) drugs. It is our practice to use propafenone, flecainide, sotalol, and dronedarone as first-line therapies in patients without structural heart disease [35]. Amiodarone is the second choice because of the risk of non cardiovascular toxicities with the latter. We occasionally choose amiodarone as a first-line therapy in elderly patients without structural heart disease for whom long-duration therapy and therefore side effects are unlikely. Patients with AF and congestive heart failure are treated with amiodarone.

Unfortunately the use of AA is often unsuccessful. Most of the data in literature report an unsatisfactory success rate of the AA drug therapy, either in interruption of acute AF episodes or in preventing recurrences. In addition secondary effects of many AA drugs advise against their use in patients with structural heart disease, thus limiting the possible choices. The most effective AA drug is Amiodarone. This drug can be used in patients with significant heart disease, mainly Coronary Artery disease and Heart Failure. This advantages are widely counterbalanced by the high incidence of significant side effects, limiting the clinical use. It was estimated that about one half of the patients receiving Amiodarone have therapy suspended in a 5 years period due to serious side effects. The disappointing long term results of drug therapy raised the interest about interventional therapies for AF.

Catheter Ablation is a percutaneous intervention aiming to modify the substrate of arrhythmias by performing thermic lesion in specific areas of the cardiac walls critically involved and responsible of the mechanism of the arrhythmia.

In the case of AF the arrhythmia is started by atrial ectopic beats (trigger) inducing desynchronization of the electrical activity of the atrium. The depolarization turns on a series of wavelets, moving into the atrium according to the possibility to find tissue to depolarize. Atrial size, dispersion of refractoriness, areas of scar tissue and orifices of vessels are all factors impacting on the maintenance of AF (substrate).

EP mapping of the atria demonstrated that most of the triggers are located into the Pulmonary Veins (PVs), were frequently repetitive ectopies (firing) were found to start AF episodes in paroxysmal forms.

Ablation into the antrum of PVs ostium may isolate the inner part of the vein, thus eliminating the trigger of AF episodes. The initial results of catheter ablation for AF were encouraging, thus spreading the indication to the procedure. Currently many and many patients affected by paroxysmal AF undergo ablation procedures.

Much more complex and honestly unreliable is the modification of the substrate. Since too many factors impact on substrate and no standardized workflow for substrate modification was clearly identified till to date, the ablation approach to this targets results both more complex and less effective in the long term. Ablation strategies adding further set of lesions to PVs isolation have been used. Linear lesions connecting PV isolation each other and to the mitral annulus or ablation of areas of abnormal electrical activity have been extensively tested in patients with persistent AF. Unfortunately long term results are still disappointing; the only multicentre randomized clinical trial performed to evaluate the best ablation strategy in such settings (STAR-AF2) was unable to demonstrate the superiority of extensive lesions in comparison to PVs isolation. Further investigations are required about this issue.

According to these observations Ablation techniques are effective in a significant percentage of patients affected by paroxysmal AF (where the trigger plays a key role) where success rate in the mid term follow-up is estimated to be as high as 75% off of antiarrhythmic

drugs. These results lead to consider ablation as a first line therapy in patients with paroxysmal clinical form and absence of significant structural heart disease (Figure 2).

The randomized MANTRA-PAF (Medical ANtiarrhythmic Treatment or Radiofrequency Ablation in Paroxysmal Atrial Fibrillation) [37] trial compared catheter ablation of AF to antiarrhythmic drug therapy as a first-line rhythm control intervention in 294 patients. At 24-month follow-up, significantly more patients in the ablation group were free from any AF and symptomatic AF. Quality of life was significantly better in the ablation group at 12 and 24 months. However, total AF burden was not significantly different between both groups. Similar information has emerged from the results of the RAAFT II (Radiofrequency Ablation for Atrial Fibrillation Trial) [38].

It is reasonable to recommend catheter ablation as first-line therapy for AF rhythm control in selected patients, i.e., those with paroxysmal AF preferring interventional treatment with a low risk profile for procedure-associated complications.

In presence of persistent or long lasting persistent AF (where the substrate is critically important and much more represented) the results of ablation in the real word is reported to be significantly less (about 50%, multiple procedures required).

In AF patients with CHA₂DS₂-VASc score ≥ 1 , catheter ablation of AF reduced the risk of the total/cardiovascular mortality and total vascular events. Atrial fibrillation recurrence predicts long-term cardiovascular outcomes, as well as the CHA₂DS₂-VASc score [39].

Figure 2. Flow chart for the therapy for suppression of AF, ESC Guidelines, 2012 [36].

Cerebrovascular complications related to catheter ablation of AF are relatively infrequent and typically occur early either during the procedure or within the first 24 h after AF ablation. Previous ischaemic stroke, peripheral vascular disease, mechanical valve replacement, and CHA₂DS₂-VASc score ≥ 3 are independent predictors of such complications. The majority of these events are ischaemic stroke with a benign clinical outcome, while intracranial hemorrhage may correlate with poor prognosis [40].

CONCLUSION

The most common serious complications of AF are stroke and thromboembolism. Medical and interventional therapies have been developed to prevent these complications. In patients with an estimated thromboembolic risk of greater than 1% to 2% per year, anticoagulation is warranted to reduce that risk and therapy is therefore strongly indicated. The recently introduced novel oral anticoagulants have been found to be at least non inferior to warfarin and, for some agents, to be superior to warfarin for the prevention of stroke and thromboembolism. In patients affected by AF with contraindications to anticoagulant therapy (mainly due to an increased risk of hemorrhage) percutaneous occlusion of the LAA is offered.

Rhythm control may significantly reduce the AF burden and subsequently the need of stroke prevention, at least in patients with no or minimal stroke risk profile. Catheter ablation is currently the most attractive option in younger patients and paroxysmal AF forms.

Clinical decision-making for stroke prevention in AF remains challenging in some patients, so a multidisciplinary approach for stroke prevention in AF is necessary. This model allows a complete assessment of patients' individual risks and ultimately facilitates clinical decision-making.

Chapter 34

SUBCLINICAL ATRIAL FIBRILLATION (SCAF) AND EMBOLIC STROKE OF UNDETERMINED SOURCE (ESUS)

Alberto Chiti*

Neurology Unit, Ospedale Sant'Andrea, La Spezia, Italy

ABSTRACT

Assessment of etiopathogenesis of ischemic stroke is essential to guide proper secondary prevention and reduce the risk of early recurrence. In spite of extensive diagnostic work-up, in about one-third of cases evaluated in routine clinical practice etiopathogenesis remains elusive (cryptogenic ischemic stroke, CIS). Thus CIS represents a very interesting arena for researchers, offering challenges and opportunities. Among the several potential causes underlying CIS, subclinical atrial fibrillation (SCAF) is one the most frequent and debated. On the other hand, the new clinical construct of embolic stroke of undetermined source (ESUS) has been recently proposed as an attempt to pragmatically overcome CIS conundrum. In both issues (SCAF and ESUS), diagnostic efforts are warranted, as they may provide the basis for trials evaluating potential benefit of anticoagulant therapy in such patients.

Keywords: subclinical atrial fibrillation, embolic stroke of undetermined source, stroke etiopathogenesis, anticoagulant therapy

INTRODUCTION

In the acute phase of ischemic stroke, assessment of etiopathogenesis is essential to implement early and proper secondary prevention therapy. To this purpose, several classification systems have been developed during time, such as Trial of Org 10172 in acute stroke treatment (TOAST) criteria [1], Causative Classification System (CCS) [2], Chinese Ischemic Stroke Subclassification (CISS) [3], Atherosclerosis-Small vessel disease-Cardiac

* Corresponding Author's Email: albertochiti@tiscali.it.

source-Other cause (A-S-C-O) system [4] and Atherosclerosis-Small vessel disease-Cardiac source-Other cause-Dissection (A-S-C-O-D) system [5]. In synthesis, while about two thirds of cases of ischemic stroke are due to a well-defined cause (large vessel atherosclerosis; cardioembolism; small vessel disease; rare causes, e.g., dissection, vasculitis or hematologic disease), in the remaining third, called “cryptogenic ischemic stroke” (CIS), diagnosis remains elusive [6]. Apart from patients with an incomplete diagnostic evaluation and more than one possible etiology (e.g., atrial fibrillation and concomitant large vessel atherosclerosis), most of CIS lack of a determined cause despite extensive evaluation.

As for antithrombotic treatment, Warfarin–Aspirin Recurrent Stroke Study - WARSS [7] randomized patients with non-cardioembolic stroke (including CIS) to warfarin (at a dose adjusted to produce an international normalized ratio of 1.4 to 2.8) versus aspirin (325 mg per day). At two years follow-up, Authors found no significant differences between aspirin and warfarin in the prevention of recurrent ischemic stroke, mortality or in the rate of major hemorrhage. Rate of minor hemorrhage favoured antiplatelet therapy, instead. However, in post-hoc analyses of the cryptogenic subgroup, warfarin was associated with worse outcomes among patients with moderate stroke severity and better outcomes among those without baseline hypertension or with posterior circulation infarcts sparing the brainstem [8]. Moreover, in a cohort of patients with non cardioembolic stroke enrolled in such study, elevated pro-B-type natriuretic peptide concentration (which is known to be associated with atrial fibrillation and heart failure) identified a subgroup of cases (about 5% of the cohort) which benefitted more from anticoagulants than antiplatelet agents [9].

As recurrence rates after CIS may be even higher than those of large artery and cardioembolic causes [10], update and refinement in both diagnosis and treatment are warranted. To afford this relevant issue, two strategies have been recently proposed. On one hand, use of advanced diagnostic techniques (e.g., cardiac telemonitoring, D-dimer/cancer screening, transesophageal echocardiography, coronary computed tomographic angiography, advanced brain and vascular imaging, neurosonological techniques) may reduce the proportion of CIS and lead to a “tailored” therapy in specific subgroups of patients. Commonly underdetected conditions include subclinical atrial fibrillation (SCAF), cancer-related coagulopathy, paradoxical/aortogenic embolism, arterogenic embolism and branch occlusive disease [11]. On the other hand, basing on the assumption that most of CIS are embolic, the pragmatic clinical construct of embolic stroke of undetermined source (ESUS) has been created as the basis for future randomized trials for secondary prevention [12]. A detailed discussion of all the potential causes of CIS is beyond the aim of this chapter, which focuses on SCAF and ESUS.

SUBCLINICAL ATRIAL FIBRILLATION (SCAF) AND CRYPTOGENIC ISCHEMIC STROKE (CIS): DATA AND CHALLENGES

Detection of SCAF: Try and Catch It!

SCAF may be the cause of stroke in almost a part of patients with CIS [13]. Underdetection of SCAF remains problematic given its unreliable symptom profile, coupled

with its intermittent nature. Prolonged electrocardiographic monitoring may identify SCAF in a subset of strokes initially categorized as cryptogenic. As oral anticoagulant therapy (OAT) is indicated for secondary prevention in cases with ischemic stroke and documented atrial fibrillation (AF, regardless of whether it is paroxysmal, persistent or permanent) [14], detection of SCAF in patients with CIS may identify further candidates to OAT (see also following sections). On these premises, diagnostic strategies to improve detection of SCAF appear justified.

Current American guidelines about early management of patients with acute ischemic stroke recommend that cardiac monitoring should be performed for at least the first 24 hours [15]. However, AF-detection rate of 24-hour Holter monitoring seems not to be sufficient, being inferior even to serial ECG for 3 days [16]. Recent technological advances have allowed to perform long-term cardiac rhythm monitoring up to months or even years after a stroke [17]. When compared with 24-hour Holter monitoring, higher rates of AF detection with prolonged in-hospital [18-22] and outpatient monitoring (even with insertable loop recorders) [13, 23-30] have been reported.

Recently, two prospective, multi-center trials have shed further light on such issue: 30-Day Cardiac Event Monitor Belt for Recording Atrial Fibrillation after a Cerebral Ischemic Event (EMBRACE) [31] and Cryptogenic Stroke and Underlying Atrial Fibrillation (CRYSTAL-AF) [32]. In the EMBRACE trial, 572 patients were randomized to either a 30-day external event-triggered loop recorder or conventional evaluation via 24-hour Holter monitor. The primary outcome was detection of AF lasting 30 seconds or longer within 90 days. The detection of AF was significantly higher in the 30-day monitoring group than in the conventional Holter monitoring group (16.1% vs 3.2%, $p < 0.001$, respectively); detection of AF lasting longer than 2.5 minutes was also greater (9.9% vs 2.5%, $p < 0.001$, respectively). In addition, in the intervention group detection rate was higher within the first 3 months after index event than afterwards (18.5% vs 9%, respectively). The CRYSTAL-AF trial introduced an internal monitoring device; 441 patients were randomized to either a insertable cardiac monitor (ICM) or standard of care with intermittent outpatient electrocardiogram monitoring. At 6, 12, and 36 months, detection rates were significantly higher in the intervention group compared to standard monitoring (8.9% vs 1.4%, $p < 0.001$; 12.4% vs 2%, $p < 0.001$; 30% vs 3%, $p < 0.001$; respectively). At 12 months, among the patients in the intervention group in whom AF had been detected, maximum AF burden resulted >6 minutes in 1 day in 92% of cases and >12 hours in 1 day in 46% of cases. Of note, EMBRACE and CRYSTAL-AF trial presented several relevant differences. First of all, type of device: noninvasive external loop recorder in EMBRACE is subject to participant compliance and may underestimate actual AF detection rates. Moreover, mean time from event to randomization: 75 vs 38 days after the stroke or TIA, respectively; of course, AF occurring prior to randomization was missed. Finally, time of monitoring: 3 vs 12 months, respectively. Despite these differences, the detection rate in the EMBRACE trial was higher, maybe due to mean age (72 vs 61 years, respectively), selection criteria (stroke evaluation was less rigorous in EMBRACE trial) and devices' detection thresholds (>30 seconds vs 2 minutes, respectively) [33].

Taken together, the above mentioned data suggest that detection rate of SCAF through long-term heart rhythm monitoring systems, which are relatively invasive and expensive, is relatively low, raising issues of cost-effectiveness [34]. Thus, a simple and cheap selection tool able to identify patients with CIS at high risk of SCAF, who would represent ideal candidates for monitoring, seems needed. To date, various predictive scores of SCAF based

on several (and sometimes complex) clinical, instrumental, laboratory and genetic factors, have been developed [9, 23, 35-43]. A detailed evaluation of routine neuroradiologic investigations, which may give relevant hints of cardioembolism (such as early hemorrhagic transformation of brain infarction [44]), has been recently included in the “cardioembolic profile” elaborated by our group [45]. In particular, considering commonly available data, we identified age older than 75 years, female sex, left atrial dilation, cortical–subcortical cerebral index infarct, ischemic lesions in multiple vascular grounds, and spontaneous hemorrhagic transformation of brain infarction as significant predictors of cardioembolic stroke due to atrial fibrillation. All of the above mentioned scores present relevant strengths and limitations and need further validation in large population before wide implementation.

SCAF and Stroke Pathogenesis: Cause or Marker?

One of the most relevant studies showing the association between SCAF and ischemic stroke was the Asymptomatic Atrial Fibrillation and Stroke Evaluation in Pacemaker Patients and the Atrial Fibrillation Reduction Atrial Pacing Trial (ASSERT) [46]. 2580 patients, aged >65 years, with hypertension and no history of atrial fibrillation, in whom a pacemaker or defibrillator had recently been implanted, were monitored for 3 months. Monitoring aimed to detect subclinical atrial tachyarrhythmias, defined as episodes of atrial rate >190 beats per minute for more than 6 minutes. Previous studies had indicated that, depending on the programming of the pacemaker, the detection of such atrial high rate episodes (AHRE) correlated well with electrocardiographic documentation of atrial fibrillation. [47]. Patients were followed for a mean of 2.5 years for the primary outcome of ischemic stroke or systemic embolism. By 3 months, subclinical atrial tachyarrhythmias detected by implanted devices had occurred in 261 patients (10.1%). Such arrhythmias resulted associated with an increased risk of clinical atrial fibrillation (hazard ratio, 5.56; 95% confidence interval [CI], 3.78 to 8.17; $P < 0.001$) and of ischemic stroke or systemic embolism (hazard ratio, 2.49; 95% CI, 1.28 to 4.85; $P = 0.007$), even after adjustment for predictors of stroke (hazard ratio, 2.50; 95% CI, 1.28 to 4.89; $P = 0.008$). Of 51 patients who had a primary outcome event, 11 had had subclinical atrial tachyarrhythmias detected by 3 months, and none had had clinical atrial fibrillation by 3 months.

ASSERT greatly contributed to renew interest in the arena of SCAF and stroke, which remains characterized by intriguing critical issues. First of all, cautious interpretations of device-detected arrhythmias are needed. Although AHREs have been used as a surrogate for AF, ASSERT investigators evaluated the positive predictive value of AHREs for intracardiac electrograms-confirmed AF and found that in 17.3% of cases AHREs were falsely positive [48]. Such results were predominantly due to repetitive non-re-entrant ventriculoatrial synchrony, also known as atrioventricular desynchronization arrhythmia.

Moreover, reported thresholds of episode duration (and their clinical relevance) are highly variable and debated [49-50]. SCAF duration ranges from 30 seconds or less (see previous sections; [51]) to 5 minutes (with 2.8 greater risk for stroke or death) [52, 53] and 24 hours (with 3.1 greater risk for thromboembolism) [54]. Likewise, a daily burden of 3.8 hours [55] and 5.5 hours [53] has also been associated with significant increases in the risk of stroke (9 and 2-fold, respectively). Several authors have attempted to integrate commonly used clinical scores (CHADS2 and CHA2DS2VASC [56, 57]) with AF episode duration/burden in

order to refine stroke risk stratification. In particular, Botto et al. [58] found a low risk of stroke (0.8%) in the following subgroups: patients with <5 minutes of AF and a CHADS2 score <2; AF lasting 5 minutes to 24 hours with a CHADS2 score <1; AF lasting >24 hours with a CHADS2 score of 0. In another paper [59], the integration of AF presence/duration/burden improved the c-statistic from 0.653 to 0.713 for CHADS2 and 0.898 to 0.910 for CHA2DS2VASc.

On top of that, even if SCAF resulted associated with an increased risk of stroke and embolism in ASSERT, a recent analysis of the study showed that very few patients had SCAF in the month before their event [60]. In particular, SCAF was detected in 26/51 patients who experienced stroke or systemic embolism during follow-up; among them, 18/26 had SCAF before stroke or systemic embolism, but only 4/18 within 30 days. The remaining 14/18 had SCAF >30 days before the event, with the most recent episode occurring at a median interval of 339 days earlier. In 8/26 cases SCAF was detected only after their stroke despite continuous monitoring (for a median duration of 228 days) before their event. Furthermore, most SCAF occurring before embolic events was far shorter than 48 hours in duration, which is commonly believed to be the minimum duration required for thrombus to form in the left atrial appendage before cardioversion [61]. Basing on both duration of episodes of SCAF and temporal relationship between SCAF and stroke, the role of SCAF in stroke pathogenesis has been called into question. Of note, among Virchow's triad (stasis, hypercoagulability, vessel wall abnormalities), prolonged (>48 hours) atrial stasis due to concomitant AF shouldn't be "conventionally" considered determinant for thromboembolism [62]. As for ASSERT patients, apart from potential non-AF related causes of stroke (such as lacunar stroke due to small vessel disease), some "non-conventional" explanations of AF-related stroke have been postulated [60]. First of all, mechanical atrial stunning after cardioversion (lasting for hours to days after electric cardioversion, as showed in echocardiographic studies [63]) may explain a delay between AF and a presumed cardioembolism. Even more interestingly, SCAF itself may not represent a cause embolism but rather a marker of "atrial cardiomyopathy" leading to embolism. AF may cause changes in atrial structure and endothelial function [64]; furthermore, it is associated with biochemical evidence of inflammation [65], markers of hypercoagulability [66] and left atrial spontaneous echo contrast [67]. In other terms, even short episodes of SCAF might trigger chronic modifications in the atria that lead to thrombus formation sometime after the actual occurrence of SCAF. On the other hand, "atrial cardiomyopathy" as a cardiac source of emboli has been reported even independently from AF. In particular, Kamel et al. found an association between baseline P-wave morphology (as expression of atrial abnormalities), incident stroke [68] and MRI-detected vascular brain injury [69], even after accounting for AF. Moreover, De Bruijn et al. [70] detected left atrial appendage (LAA) thrombus in 16% of patients with transient ischemic attack or ischemic stroke without definite cause undergoing transesophageal echocardiography. Finally, LAA volume and morphology may contribute to thrombogenesis, too. Taina et al. [71] found higher LAA volumes in patients with cryptogenic stroke patients (vs control subjects). As for LAA morphology (even if considered in patients with atrial fibrillation), "cactus," "windsock" and "cauliflower" were reported to correlate with the risk of stroke (4.08, 4.50 and 8.0 folds higher, respectively, in comparison to "chicken wing") [72]. Of note, in cases of "atrial cardiomyopathy without AF," episodes of SCAF may have been missed (depending on method of detection) and/or SCAF/AF may appear only in the late stages of atrial disease [73].

Device-Detected SCAF and Therapy: To Anticoagulate or Not to Anticoagulate?

Oral anticoagulant therapy (OAT) in patients with “conventional” AF not only reduces stroke risk [14], but also stroke severity or death [74-76], so that it is indicated (according to clinical status, evaluated by CHADS2 and CHADSVASC2 score) by international guidelines [56, 57, 77, 78]. In comparison to “conventional” AF, strong evidence about the benefit of anticoagulation in patients with “device-detected SCAF” (which may include very short episodes, whose pathogenetic role is under debate) is currently lacking. Thus, a wait-and-see approach tend to be promoted in many clinicians, who prefer to continue surveillance for additional or longer episodes of AF instead of prescribing OAT [79]. In particular, in a retrospective study of 445 pacemaker patients from a single academic hospital there was a significantly lower usage of OAT in patients with subclinical pacemaker-detected AF than in patients with clinical AF (23.7% vs 58.9%; $p < 0.001$) [80]. In another report, OAT was administered in 61.3% of patients with device-detected AF, despite a mean CHADS2 score >2 [81]. In recently published trials about device-detected AF in patients with cryptogenic stroke (EMBRACE [31]; CRYSTAL-AF [32]; see also previous sections), increased detection led to significantly increased rates of anticoagulation use. In the EMBRACE trial, 13.6% of participants in the intervention group were switched from antiplatelet to anticoagulation, compared to 4.7% of the control group participants. As for the CRYSTRAL-AF trial, a significantly greater proportion of patients were prescribed OAT in the intervention group at 6 and 12 months (10.1 vs 4.6%, $p = 0.04$, and 14.7 vs. 6.0%, $p = 0.007$, respectively); by 12 months, 97% of the participants in the intervention group with AF were prescribed OAT. Of note, an electronic survey of practice in management of patients with silent AF among European Heart Rhythm Association Research Network partners from 33 centers in 16 countries revealed a strong consensus for OAT in patients with silent AF, including those with pacemaker-detected AF, with most responders considering device-detected AF as sufficient evidence to warrant anticoagulation [82]. On the other hand, IMPACT study has recently contributed to attenuate enthusiasm about anticoagulation, showing that introducing anticoagulation early in patients with implanted devices after detection of atrial tachyarrhythmia did not improve outcomes compared to standard of care [83].

Considering the complexity of the issue of diagnosis and treatment of patients with device-detected SCAF, further research is advisable [84]. To this purpose, Apixaban for the Reduction of Thrombo-Embolism in Patients with Device- Detected Sub-Clinical Atrial Fibrillation (ARTESiA) trial is worth to be mentioned. It is an ongoing, prospective, randomized (apixaban 5 mg twice daily versus aspirin 81 mg daily), double-blinded trial to determine whether anticoagulation reduces the risk of stroke and systemic embolism in patients with device-detected subclinical AF ≥ 6 minutes without a prior history of AF [85].

EMBOLIC STROKE OF UNDETERMINED SOURCE (ESUS): A NEW PRAGMATIC CLINICAL CONSTRUCT

Most non lacunar ischemic strokes are considered embolic in their origin (as hemodynamic mechanisms, vasospasm, and in-situ thrombotic occlusion are collectively less common causes than embolism) [86, 87]. Moreover, the fact that embolic obstructions typically recanalise spontaneously, resulting in open arteries resupplying the infarcted brain, is reported as a hallmark of embolic stroke [88-92]. On these premises, in 2014 Hart et al. [12] tried to overcome the “traditionally” vague, negatively defined entity of CIS with the more clinically useful, positively defined construct of “embolic stroke of undetermined source” (ESUS). Of course, ESUS stands outside the borders of “traditionally” well-defined cause of stroke (high-risk cardioembolic sources, large vessel atherosclerosis, lacunar stroke, rare diseases such as dissection and vasculitis). ESUS etiopathogenetic umbrella may include: minor-risk potential cardioembolic sources (structural abnormalities of mitral and aortic valve, atria and left ventricle; non-atrial fibrillation atrial dysrhythmias and stasis), covert paroxysmal atrial fibrillation, cancer-associated diseases, other arteriogenic emboli and paradoxical embolism.

ESUS was “positively” defined by the following diagnostic criteria [12]:

- Stroke detected by CT or MRI that is “not lacunar.” Lacunar stroke is defined as a subcortical infarct smaller than or equal to 1,5 cm ($\leq 2,0$ cm on MRI diffusion images) in largest dimension, including on MRI diffusion-weighted images, and in the distribution of the small, penetrating cerebral arteries; visualisation by CT usually needs delayed imaging greater than 24-48 hours after stroke onset.
- Absence of extracranial or intracranial atherosclerosis causing $\geq 50\%$ luminal stenosis in arteries supplying the area of ischemia
- No major-risk cardioembolic source of embolism (permanent or paroxysmal atrial fibrillation, sustained atrial flutter, intracardiac thrombus, prosthetic cardiac valve, atrial myxoma or other cardiac tumours, mitral stenosis, recent (<4 weeks) myocardial infarction, left ventricular ejection fraction less than 30%, valvular vegetations, or infective endocarditis.)
- No other specific cause of stroke identified (e.g., arteritis, dissection, migraine/vasospasm, drug misuse)

As for diagnostic assessment for ESUS, the following work-up was proposed [12]:

- Brain CT or MRI
- 12-lead electrocardiogram
- Precordial echocardiography
- Cardiac monitoring for ≥ 24 hours with automated rhythm detection (cardiac telemetry is not considered sufficient)
- Imaging of both the extracranial and intracranial arteries supplying the area of brain ischemia (catheter, MR, or CT angiography, or cervical duplex plus transcranial Doppler ultrasonography)

Of note, imaging of the proximal aortic arch is not needed; special blood tests for prothrombotic states are suggested only if the patient has a personal or family history of unusual thrombosis or associated systematic signs or disorder.

ESUS construct is supported by neuroimaging and pathological data. In a study of thrombi visualized with susceptibility-weighted imaging compared with thrombi assessed with digital subtraction angiography in patients with middle cerebral artery occlusion, the cause of stroke remained unknown in 31 of 88 patients (35%) [93]. In 30 of these patients (96%) with cryptogenic stroke, thrombotic material was visualized with susceptibility-weighted imaging without signs of underlying atherosclerotic disease shown by digital subtraction angiography, suggesting that embolic pathogenesis was more probable than in situ thrombosis.

Moreover, in a single-center series of 303 patients with ischemic stroke, Gratz et al. [94] reported about histopathological analysis of thrombotic material retrieved by endovascular means, finding hints of thromboembolism in the 79 patients (26,1%) with ESUS (ten had erythrocyte-rich thrombi, six had platelet-rich thrombi, and 63 had mixed thrombi).

As for prophylactic treatment of patients with ESUS, two international randomized trials (RE-SPECT-ESUS [95] and NAVIGATE ESUS [96]), comparing direct oral anticoagulants (dabigatran and rivaroxaban, respectively) with aspirin are currently ongoing.

CONCLUSION

CIS has long represented a negatively defined diagnostic and therapeutic area. Recent diagnostic advancements (such as loop recorder to detect SCAF) and new clinical construct (such as ESUS) are positively defined efforts to overcome CIS limitations. Moreover, many patients with CIS may benefit from anticoagulation; on top of that, recent and future drug development has the potential to maximize risk-benefit ratio and cost-effectiveness. In spite of exciting perspectives, several etiopathogenetic, diagnostic and therapeutic issues must be further elucidated, so that on-going trials and future research are warranted.

Chapter 35

DIRECT ORAL ANTICOAGULANTS IN PATIENTS WITH ATRIAL FIBRILLATION

Foundation “Casimiro Mondino,” Pavia, Italy

ABSTRACT

Vitamin K antagonists' limitations are thought to be at least partially responsible for the underprescription of anticoagulants in a large percentage of eligible patients with atrial fibrillation. In the past few years, novel oral anticoagulants have been developed, directly blocking the activity of thrombin (dabigatran) or inhibiting activated factor X to produce anticoagulation (rivaroxaban, apixaban, edoxaban), thus also known as direct oral anticoagulants (DOACs). In patients with atrial fibrillation, DOACs have been reported to be at least equal to warfarin in reducing stroke risk and to have a better safety profile with generally fewer complications. Moreover, they do not need to be monitored by measurements of circulating levels or index of activity and are easy to manage in case of planned surgery or procedures. In this chapter we will describe findings from the recent Phase III trials investigating DOACs for stroke prevention in atrial fibrillation patients, with particular attention to topics of interest for clinical management by neurologists.

Keywords: DOACs, atrial fibrillation, ischemic stroke, cerebral hemorrhage

INTRODUCTION

Oral anticoagulation is crucial for the prevention of stroke in atrial fibrillation. Traditional vitamin K antagonists (VKA) reduce the risk of cerebrovascular events by more than 60% in patients with atrial fibrillation, but are also responsible for an increased

* Corresponding Author's Email: isabellacanavero@gmail.com.

hemorrhagic risk [1]. In addition, the need for INR monitoring prevents to get the best compliance to treatment. These limitations are probably responsible for the well-known underprescription of anticoagulants in patients with atrial fibrillation who should be treated according to guidelines [2]. A noteworthy number of patients discontinue warfarin treatment within one year from start [3]. In the past few years other oral anticoagulants have been developed: dabigatran, rivaroxaban, apixaban and edoxaban. They are known as novel, non-vitamin K dependent oral anticoagulants (NOACs) or direct oral anticoagulants (DOACs), because they directly block the activity of thrombin (dabigatran) or inhibit activated factor X (Xa) to produce anticoagulation (rivaroxaban, apixaban, edoxaban) without interfering with vitamin K-dependent coagulation factors. In patients with atrial fibrillation, DOACs have been reported to be at least equal to warfarin in reduce stroke risk and to have a better safety profile: all-cause mortality was significantly lower for DOACs compared to warfarin in large RCTs [4-7]. Moreover, they do not need to be monitored by measurements of circulating levels or index of activity. In this chapter we will discuss the most relevant features of DOACs and differences and advantages compared to traditional vitamin K antagonists. Finally, we will discuss in detail the topics of major interest from neurologists' perspective.

GENERAL OVERVIEW OF DIRECT ORAL ANTICOAGULANTS

Efficacy and Safety in Stroke Prevention

Four large randomised trials (RE-LY, ROCKET-AF, ARISTOTLE, ENGAGE-AF), including more than 72000 patients, have explored efficacy and safety of DOACs for stroke prevention in patients with atrial fibrillation eligible for oral anticoagulation with VKA [4-7]. As reported by RCT results and subsequent meta-analyses [8, 9], in atrial fibrillation patients DOACs were at least as effective as warfarin in preventing stroke (or significantly better for higher dose dabigatran and for apixaban). Also, a relative risk reduction in death of about 10% was observed. DOACs determined less serious bleeding than VKA [9]. In particular, intracranial bleeding rate was more than halved by comparison with VKA [10], although the absolute rate with warfarin is low (around 0.5% per year). In contrast, gastrointestinal bleeding with DOACs occurs 25% more often than with warfarin, with the only exception of apixaban [6]. These findings have been supported by observational analyses from registries [11, 12]. The safety advantage persists over time [13], and is particularly notable for intracranial hemorrhage.

The choice of which oral anticoagulant should be used in patients with atrial fibrillation is not mandatory according to current guidelines: the 2012 European Society of Cardiology guidelines support DOACs over VKA [14], while the 2014 American College of Cardiology / American Heart Association guidelines give DOACs and VKAs a similar level of recommendation [15]. Patients already treated with VKA should continue treatment if Time in Therapeutic Range (TTR) >60% in the last 6 months, unless concomitant bleeding conditions occur. Patients treated with VKA but with TTR ≤60% should be evaluated for a therapeutic shift to DOACs. Newly diagnosed atrial fibrillation patients should be treated with DOACs in case of practical difficulties in assessing INR values, concomitant other therapies with high risk of drug interactions, previous intracranial bleeding.

Practical considerations about the specific features of each anticoagulant could be used as guidance in targeting treatments according to individual patients' characteristics [16, 17]. For example, patients older than 80 years should be treated with dabigatran 110 mg bid instead of 150 mg bid, since the higher dosing has been associated with excess bleeding in the elderly. Patients with gastrointestinal vulnerability or previous bleedings should be treated with apixaban, since it was the only DOAC with a lower rate of GI bleedings compared to warfarin [6]. Patients with high stroke risk without significant bleeding risk could benefit from dabigatran 150 mg bid, which produced the largest reduction in risk of ischemic stroke [4], rivaroxaban or edoxaban, since they were tested on a population with a large percentage of patients with CHADS₂ score ≥ 3 (87 and 53%, respectively) [5, 7]. In patients with high stroke risk but also high hemorrhagic risk, dabigatran 110 mg bid, apixaban or edoxaban were reported to be significantly safer than warfarin [4, 6, 18].

In atrial fibrillation patients with contraindications to VKA, therapeutic options could include dual antiplatelet treatment or apixaban, as reported by the results of the AVERROES trial: in nearly 5600 VKA-unsuitable patients, apixaban reduced stroke or systemic embolism by 55% compared with aspirin with a similar risk of major bleeding (1.4%/year with apixaban versus 1.2%/year with aspirin) including intracranial hemorrhage [19].

Thanking to their efficacy, safety, ease of administration without need of anticoagulation monitoring, DOACs are expected to replace VKA in most patients. It is important to note that DOACs are more expensive than VKA. However, the extra cost for health-care systems appears to be justified by cost-effectiveness analyses [15, 20]. To date, there are no studies directly comparing the different DOACs between them.

Pharmacological Aspects

DOACs have quite predictable pharmacological effects: a fast onset of activity (2–3 h to peak effect) and a relatively short duration of action, ensuring rapid recovery of hemostatic ability in case of bleeding or planned surgery. Moreover, bridging with heparins is not required. Despite similar half-lives of about 12 h for all four drugs, dabigatran and apixaban were developed with twice per day dosing versus once per day dosing (for atrial fibrillation) with rivaroxaban and edoxaban.

Unlike VKA, DOACs have relatively few drug and food interactions; therefore anticoagulation monitoring is not required. Rivaroxaban has 40% more gastrointestinal absorption when taken with a high calorie meal, and for this reason it is generally recommended to take it with the most consistent meal of the day. Since patients with atrial fibrillation are usually treated with many drugs, when prescribing DOACs it is important to bear in mind the possibility of interactions, especially with CYP3A4 and P-glycoprotein inhibitors. However, drug interactions with DOACs are fewer than with VKA [21–25].

Contraindications

When prescribing DOACs, absolute contraindications to anticoagulants have to be considered: pregnancy, known hypersensitivity, severe ongoing hemorrhage and conditions of high bleeding risk such as hemorrhagic diathesis and platelet count $<30000/\mu\text{l}$, hepatic or

renal failure. Relative contraindications include mild to moderate ongoing hemorrhage or ulcer affecting GI tract; intracranial hemorrhage; intra or extra cranial aneurysms; pericarditis; bacterial endocarditis; previous intracranial/ endocular/ spinal/ retroperitoneal hemorrhage.

Moreover, also the exclusion criteria from the registration studies [4-7] must be kept in mind when prescribing DOACs: reduced renal function (GFR <30 ml/min for dabigatran and rivaroxaban, <25 for apixaban); uncontrolled hypertension; current hepatopathies; platelet count <100000/ μ l; concomitant treatment with acetylsalicylic acid (ASA, >100 mg die for rivaroxaban and >165 mg die for apixaban) or with ASA plus clopidogrel (apixaban); recent treatment with ASA plus thienopyridines in the last 5 days (rivaroxaban); recent treatment with intravenous antiplatelets or fibrinolytics (in the last 48 hours for dabigatran, in the last 5 days for rivaroxaban) [4, 5]. In addition, DOACs should not be prescribed in patients with atrial fibrillation and significant valvular disorder.

Concomitant therapies should always be considered to avoid drug interactions.

Adherence Issues

VKA efficacy is considered to be strictly depending on patients' compliance. However, besides the advantages in management, also DOACs can be problematic in case of poor adherence because of their short half-life. Especially when DOACs are administered once a day, one missed dose results in low trough drug concentrations. Moreover, a routine measurement of the effect of the drug is not currently available for DOACs, making more difficult to assess the quality of patients' compliance [26]. However, adherence to DOACs in atrial fibrillation patients does not seem to be different from that of warfarin (75% in the case of dabigatran) [9, 27, 28].

Some problems in clinical management could arise from suboptimal adherence. In the absence of conclusive data from RCTs, practical guidelines have been proposed by experts [18]. For example, a missing dose could be made up within 6 hours for drugs that are usually taken every 12 hours and within 12 hours for drugs usually taken every 24 hours. After these timings, the dose must be "skipped." If the dose has been erroneously taken twice, it is suggested to skip the following dose for drugs usually taken every 12 hours and instead to keep the following habitual dose for drugs usually taken every 24 hours. If it is not possible to ensure the effective ingestion of the last dose, for drugs usually taken every 12 hours no additional dose is required, while for drugs usually administered every 24 hours it is advised to take another dose.

PRESENCE OF COMORBIDITIES

Chronic Kidney Disease

DOACs have renal clearance, especially dabigatran (80%). In fact, the assessment of creatinine clearance is fundamental to choose and determine dosing of these drugs. DOACs have not been clinically studied in patients with stage IV chronic kidney disease (creatinine

clearance <30 mL/min), therefore are contraindicated in such patients; moreover, the inefficient drug elimination by kidneys can result in drug accumulation, and thus in increasing hemorrhagic risks. Patients with milder chronic kidney disease (creatinine clearance 30-50 mL/min) could be treated with reduced doses of dabigatran (110 mg bid), rivaroxaban (15 mg) and edoxaban (30 mg); in patients with creatinine ≥ 1.5 mg/dL, dosing of apixaban should be reduced to 2.5 mg bid only in case of concomitant age ≥ 80 years and/or weight ≤ 60 kg. Rivaroxaban and apixaban should be preferred considering the lower rate of renal excretion [26]. In addition, regular kidney function checks should be performed especially in elderly patients.

Acute Coronary Syndromes

20-40% of patients with atrial fibrillation have concomitant coronary artery disease [29]. The combination of oral anticoagulants and antiplatelet therapy for patients with an indication for both is challenging, mainly because of the increased bleeding risk [30]. Since VKA are effective in preventing coronary thrombotic events, current European guidelines for atrial fibrillation management discourage the use of antiplatelet therapy for patients with stable coronary disease treated with oral anticoagulants [14]. In patients undergoing percutaneous coronary intervention, especially in the setting of acute coronary syndromes, during and after the procedure potent antiplatelet therapy is needed to prevent thrombotic complications including stent thrombosis. In such cases dual antiplatelet therapy (aspirin plus clopidogrel) is added to VKA for at least one year after the intervention with any type of stent used [31, 32].

Thanking to their proven safety, using DOACs instead of VKA could be an option to reduce the risk of bleeding. At least two RCTs have been initiated and are currently ongoing to evaluate the safety and efficacy of a DOAC versus VKA in atrial fibrillation patients undergoing coronary intervention for either stable coronary disease or acute coronary syndrome [26]. European Society of Cardiology - European Heart Rhythm Association (EHRA) guidelines state that patients with atrial fibrillation and acute or stable coronary artery disease who require angioplasty and/or stenting, can be treated with a DOAC plus single or dual antiplatelet according to their bleeding risk and the clinical setting [33].

Elderly Patients

Elderly patients have been considerably studied in the registration studies for DOACs: 7258 in the RE-LY (4828 of which were treated with dabigatran), 6164 in the ROCKET (3082 receiving rivaroxaban), and 5678 in the ARISTOTLE (2850 treated with apixaban) [4-6].

Older age is a strong risk factor for both ischemic and hemorrhagic stroke. Older patients treated with dabigatran had a relatively greater risk of bleeding versus warfarin and compared with younger patients [34]. Accordingly, the European Society of Cardiology recommends the lower dose of dabigatran (110 mg bid) for patients aged ≥ 80 years [14]. Oral Xa inhibitors had a relative risk of bleeding versus warfarin quite similar in elderly patients compared with younger patients [35, 36].

The risk of overdosage of DOACs in the elderly is increased owing to the common renal impairment, low body weight and drug interactions [37]. A periodic monitoring of renal function by means of creatinine clearance assessment is therefore recommended.

Adherence to DOACs is of major importance due to their short half-lives. Elderly patients could have more adherence issues than younger patients; therefore the introduction of these treatments should be carefully discussed also with caregivers.

Reversal Strategies and Management of Bleedings

DOACs are associated with lower, but not absent, occurrence of bleedings. In case of serious hemorrhage, assessing anticoagulation status might be crucial. Since DOACs half-lives are about 12 h, to determine the timing of the last ingested dose allows estimating the anticoagulation status. To date, few accurate tests are commonly available. Dabigatran influences the activated partial thromboplastin time (aPTT): a normal aPTT suggests relatively little dabigatran effect. Also, dabigatran plasma drug level is directly correlated with anticoagulation effect [38]. Rivaroxaban usually produces at least slight elevation of the prothrombin time (PT). A modified thrombin time and anti-factor Xa assays are commercially available to establish the effect of dabigatran and direct Xa inhibitors, respectively; however, these assays are neither widely nor rapidly available in the emergency settings. Creatinine level should be measured to assess renal function and estimate the rate of anticoagulant drug clearance.

In case of serious bleeding, patients should be hospitalized. Clinical management is based on: stop of any antithrombotic therapy, identification of the source and local strategies to produce hemostasis. Within 2–4 h from DOAC ingestion, oral activated charcoal will reduce absorption. Fluid resuscitation and blood transfusions might be indicated according to blood panel. Reversal of other antithrombotics should be considered (for example platelet transfusion if ongoing treatment with aspirin). If treated with dabigatran, patients could benefit from hemodialysis (particularly if aPTT >80 sec), frozen fresh plasma or desmopressin acetate. Restoration of coagulation could be partly achieved by the administration of prothrombin complex concentrate [39] or activated factor VII, although no clinical evidence or practice guidelines are currently available. Similar strategies can be applied in case of need of urgent, not extensible surgery.

In patients treated with VKA a reversal strategy with vitamin K and coagulation factors is well established, although not always associated with better outcome owing to delayed efficacy. In contrast, antidotes for DOACs are not yet routinely available, although reversal agents have been currently developed and are currently studied in clinical settings [40–42]: idarucizumab is a humanized monoclonal antibody against dabigatran, which has been recently approved by FDA [43]; andexanet is a decoy (truncated) factor Xa molecule that binds Xa blockers; finally, PER977 binds non-specifically all DOACs [26, 44].

Although relatively uncommon by comparison with VKA, intracranial bleeding occurs also in patients on DOACs. Intracranial hemorrhage in association with any oral anticoagulant has a poor prognosis, independently on reversal strategies whose impact on clinical outcome is unclear. According to this perspective, the use of DOACs could be supported because it is associated with lower rate of intracranial hemorrhage compared to VKA.

Gastrointestinal bleedings are instead more common during DOACs (with the only exception of apixaban) than VKA therapy. Patients with medical history of gastrointestinal bleeding have to be carefully examined if having indication to DOACs. Concomitant treatment with proton-pump inhibitors could be considered, although there is no evidence supporting this strategy. Concomitant treatment with non-steroidal anti-inflammatory drugs and antiplatelets, which is associated with higher rate of major bleeding [30, 45], should be avoided, unless clearly indicated.

Switching between Anticoagulants

When switching an eligible patient from VKA to a DOAC, the gap in therapeutic anticoagulation status must be the shortest possible to avoid thrombotic events [46]. After stopping VKA, when INR has dropped to around 2.0 or less, the DOAC should be initiated. Bridging with parenteral anticoagulation is not generally advised.

When switching from a DOAC to VKA is required (for example for deteriorating renal function), due to the slow onset of action of VKA, the DOAC and VKA should be given concomitantly until the INR is around 2.0. Since oral direct factor Xa blockers affect INR early after intake, INR should be checked immediately before the next DOAC intake during the concomitant administration period, and retested 24 h after the last DOAC dose to ensure that the patient is in therapeutic range on the VKA. After the transition is completed frequent INR checks should be made, as in any other patient being initiated on a VKA.

For patients treated with LMW heparin, start the DOAC when the next LMW heparin is due. For conversion from a continuous heparin infusion, DOAC should be started immediately when infusion ceased. To convert from DOAC to unfractionated or LMW heparin, these have to be started 12-24 hours after the last DOAC dose (no bolus dose of unfractionated heparin is required). It is better to wait 48 hours if ongoing treatment with dabigatran and creatinine clearance < 30 ml/min.

Management in Case of Planned Cardioversion

Among DOACs, only rivaroxaban has completed a Phase III clinical trial with the specific indication for anticoagulation of patients undergoing electrical or pharmacological cardioversion, resulting to be effective and safe as warfarin [47]. Practical recommendations from EHRA suggest that cardioversion is acceptably safe in patients treated with any DOAC: in fact, in the registration studies the subgroups of patients undergoing cardioversion treated with DOACs always showed lower rates of complications compared to warfarin [18]. DOAC treatment should be initiated 3 weeks before the procedure, and continued at least for other 4 weeks after. In case of uncertain compliance, transesophageal echocardiography should be performed before cardioversion to ensure the absence of intracardiac thrombosis.

Management in Case of Planned Surgical Interventions

Thanking to their short half-lives, DOACs are of easy management in case of planned surgery. It can be hypothesized that a brief suspension of treatment would result in reversal of the anticoagulant effect without need of bridging with heparins, in contrast with VKA.

However, few data from clinical experience in such settings are currently available. To date, the only recommendations come from experts [18]. Generally, in such conditions it is important to consider: patients' features (age, renal function, ongoing treatments), drug features and hemorrhagic risk related to the procedure.

Low bleeding risk procedures include: endoscopic procedures with bioptic sampling, prostatic or bladder biopsy, pacemaker implantation, electrophysiological procedures, radiofrequencies ablation, angiography. In patients with normal kidney function, procedures should be planned at least 24 hours after the last DOAC administration. In patients with reduced renal function, the procedure could be performed at least 36 and 48 hours after last dose of dabigatran if GFR 50-80 and <50 ml/min, respectively, and 36 hours after last dose of apixaban or rivaroxaban if GFR 15-30 ml/min. A very low hemorrhagic risk is usually hypothesized in cases of odontoiatric interventions and dental avulsion, surgical corrections of cataract and glaucoma, minor dermatological interventions (especially if effective local hemostatic measures could be applied), and also endoscopic procedures without bioptic sampling. In these cases DOAC treatment should not be suspended especially if the intervention could be planned during the end of the therapeutic window of the drug (12 hours after last dose for dabigatran and apixaban and 24 hours after last dose of rivaroxaban). Subsequently, patients should be carefully observed to ensure efficacy of local hemostatic measures. After low and very low risk procedures, DOACs can be restarted after 6-8 hours [18].

Procedures with high hemorrhagic risk include: lumbar puncture, epidural anesthesia, neurosurgery, esophageal varices ligation, endoscopic removal of polypi, sphincterotomy and dilation of stenosis, thoracic and abdominal surgery, orthopedics, hepatic or renal biopsy, transurethral resection of prostate. In those cases, treatment with DOACs should be managed under strict surveillance of expert specialists in coagulative disorders. To get a minimal residual anticoagulant effect (<3-6%) at the time of surgery, it has to be planned to stop DOAC ingestion 4 or 5 drug half-lives before [48]. Bleeding risk can also be minimized adjusting the time when anticoagulant is resumed. For patients at high risk for thromboembolism, it is possible to restart with a reduced dose of dabigatran or rivaroxaban 12-24 hours after the procedure, and resume the full dosage only after 48-72 hours. Patients with low ischemic risk could wait 72 hours or more after surgery [48]. Patients with subsequent need of immobilization should be treated with prophylaxis for deep venous thrombosis (LMW heparin) 6-8 hours after the intervention and then restarting DOAC after 48-72 hours.

DOACs FROM NEUROLOGIST'S PERSPECTIVE

DOACs usually come to neurologists' attention in some specific clinical scenarios. In this section we will describe the more common clinical settings where DOACs have to be prescribed or managed by neurologists.

Secondary Prevention of Ischemic Stroke in Patients with Atrial Fibrillation

The CHADS₂ or the newer CHA₂DS₂-VASc scores are useful clinical tools in determining the appropriateness of initiating anticoagulation therapy in patients with atrial fibrillation. In both scoring system two points are assigned for medical history of TIA or stroke, and a final score of 2 or greater is considered high risk and gives recommendation for oral anticoagulation. Therefore, atrial fibrillation patients suffering from a cerebrovascular event should invariably deserve oral anticoagulants if not contraindicated.

Considering the study features of the main RCTs, patients with a medical history of one or more previous cerebrovascular events should benefit more and therefore be treated with apixaban, which was associated with the largest reduction of risk compared to warfarin [6], or rivaroxaban, since more than half (55%) of the patients tested in the ROCKET-AF trial experienced previous strokes [5]. Dabigatran at the dose of 150 mg bid was actually shown to be superior to warfarin for stroke prevention, but only nearly 20% of the studied population suffered from previous cerebrovascular events [4].

Adherence Issues in the Elderly and in Patients with Cognitive Impairment

As we previously outlined, keeping adherence to DOACs is crucial due to their short half-lives. Neurologists have often to manage patients with older age and possibly cognitive impairment. In particular, adherence to oral anticoagulation seems to be hampered mostly by reduced levels of physical and functional abilities (assessed by ADL and IADL scores), rather than by the presence of cognitive impairment itself (MoCA score <26) [49]. To ensure the best adherence to treatment, before prescribing anticoagulants neurologists should carefully focus on cognitive and mental status, gait performances and global disability, to assess what kind of supervision may be necessary for the patients, and discuss the features of the treatment with caregivers.

The Acute Phase of Stroke

The use of anticoagulants in acute stroke patients has been proposed to avoid neurological deterioration, to prevent cardioembolic recurrences and to improve outcome. Acute treatment with unfractionated heparin, LMW heparin or heparinoids for the acute phase of stroke showed in some studies a reduced rate of early ischemic events, but the overall clinical benefit was abolished due to increased hemorrhagic events [50-52]. Hemorrhagic transformation is a common complication after cardioembolic stroke, although is often asymptomatic. However, it is also true that anticoagulants increase risk of intra- and extracranial hemorrhage by 2%. Therefore, it would be safe stratifying patients according to their bleeding risk (considering stroke volume, expected spontaneous or thrombolysis-induced reperfusion timing, arterial pressure) to avoid early anticoagulation especially in high-risk cases, for which it is usual practice to wait about two weeks before starting anticoagulants. In any case, the use of anticoagulants in the acute phase of stroke is not supported by evidence (the fewer recurrent ischemic strokes were offset by an increase in extracranial bleedings) [53] and thus not recommended by current guidelines, which instead

suggest the use of aspirin within 24-48 hours from stroke onset [54]. However, a recent study found that the best timing to start anticoagulation in secondary prevention of stroke is between 4 and 14 days from stroke onset: this timing was associated with a lower rate of a composite outcome measure considering cerebral and systemic embolism and cerebral and systemic bleeding [55]. Although DOACs have been associated with fewer hemorrhagic complications than warfarin, it is important to point out that the registration studies explicitly excluded patients in the acute phase of stroke (within 14 days for dabigatran and rivaroxaban, within 7 days for apixaban and within 30 days for edoxaban), therefore no data about safety and efficacy in such conditions can be deduced. Recently, some ongoing trials are exploring risks and benefits of acute treatment with DOACs [56, 57].

Moreover, it is important to note that also recent treatment with thrombolysis was considered an exclusion criterion in some of the DOACs registration studies (performed in the last 5 days for rivaroxaban, in the last 48 hours for dabigatran), therefore no data about safety of starting treatment with DOAC in patients with acute stroke undergoing thrombolysis are currently available.

Ischemic Stroke Recurrences during Treatment with DOACs

Unfortunately, also patients treated with DOACs could suffer from acute ischemic stroke recurrences.

Acute Intervention Strategies

An ongoing effective treatment with anticoagulants would contraindicate thrombolytic therapies. With VKA, testing INR allows to directly assess the anticoagulation status. With $\text{INR} \leq 1.7$, intravenous thrombolysis can be performed [54, 58]; if not, the only option to consider is an endovascular approach. Management of ischemic recurrences during treatment with DOACs is more challenging due to the absence of a reliable anticoagulation index. Therefore, to determine the timing of the last ingested dose becomes crucial. If it can be ensured that the last dose was taken at least 48 hours before, and laboratory tests give normal values of INR, PT and aPTT, there would be enough confidence to treat the patient safely. If it is not possible to determine the last DOAC administration, some laboratory values could help the decision-making process. It is useful to remember that the aPTT is moderately increased by dabigatran, but not by Xa-inhibitors, which instead modify PT and INR (only at their peak concentration). Unfortunately, the more specific and reliable tests assessing DOACs' activity are not commonly available in hospitals and emergency settings. They are thrombin time (TT, and the more appropriate diluted thrombin time – dTT or Hemoclot), ecarin clotting time (ECT), both notably increased during treatment with dabigatran, and anti-factor Xa activity (increased by direct Xa-inhibitors as well as by LMW heparin) [59]. If it is not possible to determine the timing of last DOAC ingestion but common laboratory tests (aPTT, INR) are normal, the suspect of an inadequate anticoagulation can only be partially supported, and thus it would be better to carefully discuss with patients and caregivers the risks of an eventual intravenous thrombolysis. Or, if neuroimaging gives evidence of a proximal arterial occlusion, endovascular procedures could be considered. If thrombin time

and ecarin clotting time are available, their normality after 4 hours from the last dabigatran ingestion could exclude a clinically relevant anticoagulation. Similarly, anti-factor Xa activity after 5 hours from the last Xa-inhibitor rules out its effect [60, 61]. Thus, emergency treatment with alteplase could be applied. Within at least 12 hours from last dabigatran dose and $TT < 4$ times the upper limit of the normal range and/or $ECT < 2$ times the upper limit of the normal range, intravenous thrombolysis could be proposed, carefully evaluating pros and cons, as well as intrarterial approaches [59].

Implementation of Secondary Prevention Strategies after their Failure in Preventing Recurrences

As already mentioned, Phase III trials did not explore the effect of DOACs in the acute phase of stroke [4-7]. Therefore, after the occurrence of an ischemic event during treatment with DOACs, restarting anticoagulation can be challenging. EHRA practical guidelines suggest that continuation of DOAC treatment should be made according to the stroke volume. It is suggested to restart DOAC one day after a TIA, three days after a small, no disabling stroke, six days after a moderate stroke and at least 12 days after a large stroke (the so-called “1-3-6-12” rule) [18]. Ischemic recurrences occurring during adequate DOAC treatment do not allow increasing the dosage, in contrast with the traditional, quite common practice of increasing target INR with VKA. A good practice would be to carefully examine the etiology of the stroke recurrence, assess comorbidities and recalculate the ischemic risk of the patients. An acute lacunar syndrome should lead to implement pharmacological control of the more common risk factors: hypertension and diabetes. In the presence of some comorbidities (ischemic cardiopathy, severe atherosclerosis), the addition of an antiplatelet could be considered. However, particular attention should be made, since Phase III trials considered as contraindications to randomization a concomitant treatment with acetylsalicylic acid (ASA, >100 mg die for rivaroxaban and >165 mg die for apixaban) or with ASA plus clopidogrel (apixaban) and recent treatment with ASA plus thienopyridines in the last 5 days (rivaroxaban) [5, 6]. Still, the clinician must consider the higher bleeding risk associated with these changes, and this must be communicated to the patient.

Intracranial Hemorrhage

Intracranial hemorrhage is the most devastating complication of oral anticoagulation, determining high mortality and disability in survivors. Although infrequent, intracranial bleeding can occurs also in patients treated with DOACs. It has been reported that a cerebral hematoma arising during dabigatran treatment tends to remain small without significant expansion [62]. However, intracranial bleeding associated with any antithrombotic treatment is often affected by a poor prognosis.

The absence of approved specific reversal strategies further affect clinical management of this condition. Hospitalization and general measures for acute bleeding have to be urgently applied (see above) and laboratory tests performed in order to plan eventual strategies to anticoagulation reversal and fluid or blood transfusions. However, the impact of anticoagulation reversal on clinical outcome has not been sufficiently explored. To date, the

best clinical practice against bleeding is therefore based on its prevention. DOACs could be preferred over VKA due to the lower incidence of intracranial hemorrhage. Then, it is important to carefully evaluate the risk profile of the patients that could receive antithrombotics before prescription.

Clinical and Neuroimaging Tools to Stratify Hemorrhagic Risk

To date, there are a few clinical tools that may guide clinicians in assessing bleeding risk. The HAS-BLED scoring system has been recently incorporated into the European Society of Cardiology guidelines for management of atrial fibrillation, although it requires further validation. This scoring system assigns 1 point for each of the following risk factors: hypertension, abnormal renal function, abnormal liver function, medical history of stroke, previous significant bleeding, labile INR, age older than 75, chronic use of aspirin/ NSAIDs, chronic use of drugs or alcohol. A score ≥ 3 or greater than the CHADS₂ score, it is assumed that bleeding risk outweighs the potential benefit of oral anticoagulants [63, 64]. Besides HAS-BLED items, congenital or acquired coagulative disorders, ulcerative GI disease are other not uncommon conditions associated with an increased hemorrhagic risk. If treated with anticoagulants, these patients have to be routinely checked with periodic blood count and in search also for minor bleeding (for example, occult bleeding in stools or urine).

Besides risk scores, recently brain imaging (in particular, MRI) has been proposed as another clinical tool to assess potential complications and predict outcome of anticoagulant treatment. Cerebral microbleeds are defined as small, round areas of hypointensity on the gradient echo T2-weighted magnetic resonance sequences, and are believed to represent perivascular accumulation of hemosiderin-containing macrophages, suggesting vulnerability of the cerebral small vessels. Cortical microbleeds are currently thought to be manifestations of cerebral amyloid angiopathy, while deep hemisphere lesions would be indicative of hypertensive arteriopathy. They have been hypothesized to be a biomarker for bleeding-prone small vessel pathology, and thus could predict future risk of developing symptomatic intracerebral bleeding. Cerebral microbleeds have been described in association with other conditions expressing vulnerability of cerebral small vessels: older age, hypertension, smoke, lacunar infarcts, prior ischemic strokes or intracranial hemorrhages, white matter disease, and Alzheimer disease. Some of these conditions overlap with CHA₂DS₂-VASc items, indicating that this pro-hemorrhagic cerebral condition can be likely associated with a high ischemic risk. White matter changes are another condition that can affect cerebral ageing to various extents, the more severe known as leukoaraiosis, and have been shown to be strongly related to presence of cerebral microbleeds [65], suggesting a common microvascular etiology for both. However, the predictive value of white matter disease detected by MRI for anticoagulant-related intracranial hemorrhage is not currently known [66].

Table 1. Summary of DOACs features

DOAC name	Dabigatran	Rivaroxaban	Apixaban	Edoxaban
Trade name	Pradaxa	Xarelto	Eliquis	Savaysa, Lixiana
RCT Registration study	RE-LY	ROCKET-AF	ARISTOTLE	ENGAGE-AF
Design	Open label	Blinded	Blinded	Blinded
Mean CHADS ₂ score	2.1	3.5	2.1	2.8
Target	Factor IIa	Factor Xa	Factor Xa	Factor Xa
Daily dosing	2	1	2	1
Renal clearance	≈80%	≈35%	≈25%	≈50%
Elimination by means of hemodialysis	Yes (68%)	Partial	No	No
Biodisponibility	3-7% (keep intact capsules to avoid increased Biodisponibility)	66% fasting, 100% after meal	50-60%	62%
Effect of food on drug absorption	None	Increased	None	None
Effect of PPI on drug absorption	Reduced (12-30%)	None	None	None
Time to peak concentration	1.25-3 h	2-4 h	3-4 h	1-2 h
Half-life	12-17 h	5-9 h (11-13 h if age ≥75 y)	8-15 h	8-10 h
Time of anticoagulant effect reversal	24 h	24 h	24 h	24 h
Dose	150 mg bid / 110 mg bid (if age ≥80 y, creatinine clearance 30-50 ml/min, high bleeding risk or concomitant therapy with verapamil)	20 mg / 15 mg (if creatinine clearance 30-50 ml/min)	5 mg bid / 2.5 mg bid (if 2 of the following criteria are met: age ≥80 y, weight ≤60 kg, creatinine ≥1.5 mg/dl, or if creatinine clearance 15-29 ml/min)	60 mg / 30 mg (if creatinine clearance 30-50 ml/min, weight ≤60 kg or strong P-glycoprotein inhibitor)
Metabolism	P-glycoprotein	P-glycoprotein and CYP3A4	P-glycoprotein and CYP3A4	P-glycoprotein
Drug interactions	Atorvastatin, PPI, NSAIDs, ketoconazole, dronedarone, rifampicin	Ketoconazole, itraconazole, voriconazole, posaconazole, ritonavir, rifampicin, azithromycin, phenytoin, carbamazepine, phenobarbital, diltiazem, verapamil, hypericum	Diltiazem, verapamil, azithromycin, hypericum	Ketoconazole, quinidine, erythromycin, amiodarone
Food interactions	None*	None*	None*	None*
Binding to plasma proteins	35%	85%	90%	50%

Table 1. (Continued)

DOAC name	Dabigatran	Rivaroxaban	Apixaban	Edoxaban
Preferred laboratory test / Emergency scenario test	Dilute thrombin time / Accelerated partial thromboplastin time	Anti Xa-concentration / Prothrombin time	Anti Xa-concentration / Diluted prothrombin time	Anti Xa concentration /No data available
Antidote	Idarucizumab PER977	Andexanet alfa PER977	Andexanet alfa PER977	Andexanet alfa PER977

* With the exception of grapefruit juice, which is a well-known strong P-gp inhibitor.

A brain MRI has been proposed as an additional tool to stratify hemorrhagic risk. The presence of cortical microbleeds or at least five subcortical microbleeds would discourage traditional vitamin K-dependent anticoagulation, while novel anticoagulants would be acceptable. The development of any neurological changes during treatment with anticoagulants would indicate to perform a follow-up MRI to investigate potential microbleed progression. Due to the high costs of the technique, MRI screening could be applied in some particular settings to help the decision-making process, for example in patients with intermediate CHADS₂ scores, or in patients whose fall risks or cognitive impairment could increase bleeding risk [66].

Restarting DOACs after Intracerebral Hemorrhage

After an anticoagulant-associated intracerebral hemorrhage, the resumption of anticoagulation has to be carefully evaluated, by considering thromboembolic and hemorrhagic risks, the treatment history with anticoagulation, the causes of the hemorrhages, the comorbidities of the patient, the risk of hematoma growth. Patients with typical, deep hemispheric intracerebral hemorrhage and a CHA₂DS₂-VASc score ≥5, may benefit from restarting anticoagulation, which basing on the available data would reasonably be after 10 weeks although some works have suggested an earlier resumption [67, 68]. A careful assessment of other pro-hemorrhagic conditions, for example uncontrolled hypertension, should be done and risk factors addressed with adequate treatments [69]. In patients with atypical (lobar) cerebral hemorrhage or cerebral amyloid angiopathy, the risk for anticoagulant-related hemorrhagic recurrences is higher than the thromboembolic risk and for this reason anticoagulation should be avoided [67]. Non-pharmacological prevention strategies of thromboembolism, such as surgical ablation or left atrial appendage occlusion, should be evaluated as alternatives to anticoagulants [70, 71].

CONCLUSION

A large proportion of patients with atrial fibrillation and risk of stroke, although eligible for anticoagulation, are treated suboptimally. The oral direct inhibitors of factors IIa or Xa provide an important alternative to traditional VKA, being at least as effective as warfarin for stroke prevention in atrial fibrillation with a more favorable safety profile, especially in terms

of reduced intracranial bleeding, and potentially easier adherence. To date, the difficult reversal of DOACs effects has not significantly worsened bleeding outcomes. However, the safe management of these drugs requires experience and knowledge about their pharmacological properties, contraindications and specific clinical indications.

ABSTRACT

Stroke is a multifactorial event, resulting from the combination of genetic and environmental determinants. The first are more influent in younger patients, while the importance of the environmental factors increase with the age of patients. Biomarkers are thus needed, especially in older persons, to define the current risk, as it results from the individual combination of genetic predisposition, environmental exposure, and clinical history.

The presence of atherosclerosis is a major cause of stroke. The well established risk factors for atherosclerosis (e.g., dyslipidaemia, hypertension, diabetes, obesity) allow the identification of patients at higher risk of vascular events, nevertheless, a large proportion of events still occur, even in patients apparently at low risk. Thus new biomarkers are needed to better identify high-risk patients, and to achieve further insights into the pathogenesis of stroke and its causative conditions.

In the first part of this chapter, inflammation, thrombosis, oxidative stress are discussed as possible source of biomarkers of plaque progression and destabilization. In the second part, serum gamma-glutamyltransferase is presented as a novel marker for cardiovascular prognosis related to atherosclerosis.

Keywords: stroke, biomarkers, atherosclerosis, gamma-glutamyltransferase

INTRODUCTION

Stroke is a multifactorial event, resulting from the combination of genetic and environmental determinants. Genetic factors have been found to contribute to the risk of stroke in several ways, and at multiple levels of its pathogenesis, e.g., by increasing susceptibility to conventional risk factors, by enhancing the potency of their effects, or simply as additive independent pathogenic factor [1]. In younger patients, extensive molecular genetic studies, and in particular the adoption of Genome-Wide Association Study approach, will help identifying new genes contributing to the risk of stroke, and improving several aspect of the clinical management of the disease. Nevertheless, it is quite obvious that especially in older patients the influence of the environment on the risk of stroke is proportionally larger; cardiovascular disease, and atherosclerosis in particular, are a major cause of stroke, and the individual atherosclerotic burden, and consequently the risk profile, largely results from the combination of genetic predisposition and of the severity/duration of environmental influences, such as individual behaviour, lifestyle, professional exposure, previous or current disease etc., that may contribute to the onset and progression of the conditions at the basis of stroke. Biomarkers are thus needed, especially in older individuals, to define the current risk, as it results from the individual combination of genetic predisposition, environmental exposure, and clinical history.

In this perspective, the understand of the role of cholesterol in the pathogenesis of the atherosclerotic plaque, the elucidation of the biochemical and molecular aspects of cholesterol synthesis, the development of a suitable clinical interpretation of serum cholesterol levels, the development of inhibitors of the endogenous cholesterol synthesis, have been an extraordinary achievement of modern medicine, and an example of fruitful interaction between basic and clinical research, which already allowed to interfere directly with evolution of extracranial and intracranial atherosclerosis and related events, and had a recognized effect in reducing the individual risk of stroke. Nevertheless, a large proportion of events still occur, even in patients apparently at low risk, or despite prevention, thus making urgent the identification of new biomarkers that may allow the identification of high-risk population deserving a more aggressive intervention, but also to be used as tools to achieve further insights into the pathogenesis of stroke and its causative conditions.

THE PATHOLOGICAL BASIS OF ARTERIAL WALL INFLAMMATION

The clinical sign of atherosclerosis is the formation of the fibro-lipid plaque (atheroma) in the wall of the large- and medium-size arteries. These lesions are extremely common in adults, and their natural history proceeds very slowly, spanning all over the entire life. The initial phase of the lesion is represented by endothelial damage that favours the accumulation of oxidized lipids and cellular infiltration of the intima; this lesion can evolve into a fibro-lipid plaque. This second phase is characterized by the simultaneous formation of a core, where oxidized lipids and cellular elements of phagocytic nature accumulate, and of a fibrous cap that serves as a container for the inflammatory tissue [2]. Over the decades, the progressive growth of the lesion, due both to the accumulation of material and to the proliferation of reactive cellular elements, can determine its protrusion in the vascular lumen

with progressive reduction of blood perfusion of tissue placed downstream of the affected vessel. This phenomenon may have morphological (atrophy and remodelling) as well as functional (failure) consequences on the affected tissue. The most dangerous and frequent consequences of atherosclerosis consist in acute events such as myocardial infarction and stroke, due to the sudden obstruction of blood flow in the vessel affected by the atheroma, caused by thrombotic or intra-plaque haemorrhagic events, largely independent of the size of the lesion [3-6].

Most of the individuals carrying plaques will never develop clinical consequences of atherosclerosis, and, for this reason, in the follow-up of patients with evidence of atherosclerosis a particular attention is devoted to the identification of those at a high risk of developing acute events, deserving a more intensive intervention [7-10].

The occurrence of the individual clinical consequences of atherosclerosis depends on the specific structural evolution of the lesions, thus on biochemical and molecular events occurring within the plaques. In the case of chronic consequences, proliferative and hyperplastic aspects prevail causing the lesion to progressively protrude into the vessel and to reduce the lumen. In the case of acute events, instead, the plaque undergoes structural alterations resulting in the thinning of the fibrous cap (unstable plaque). This situation makes the unstable plaque prone to rupture and to loose the lining endothelium, thus allowing the highly pro-coagulant content of the lesion to get in contact with blood, triggering thrombus formation and acute vessel obstruction. The presence of an unstable plaque can be associated with characteristic clinical syndromes, such transient ischemic attacks, which precede the critical events [3, 11].

INFLAMMATION AND THROMBOSIS AS A SOURCE OF BIOMARKERS

The mature atherosclerotic plaque consists in an intra- and extracellular accumulation of oxidized lipids within the arterial wall, surrounded by a variable amount of fibrous tissue; however, it is now clear that the biochemical, molecular, and cellular events triggering its onset and determining its progression, evolution, and eventually its instabilization and rupture are to be viewed in the context of the inflammatory response [12].

Inflammatory signals are responsible for the increased permeability of the endothelial cells that leads to enhanced insudation of LDL into the arterial wall, for the migration, proliferation, and differentiation of inflammatory cells and fibroblasts driving the oxidation of LDL, the formation of the necrotic gruel and its fibrous cap, for the release of proteases and their tissue inhibitors driving plaque remodelling, and in general for the key events determining the different evolution of the plaque towards stabilization or instabilization and rupture [12]. On the other side, through the regulation of the production of plasma proteins involved in the blood clotting and fibrinolysis, the systemic inflammatory response influences also the liability of blood to sustain the thrombo-embolic events occurring in correspondence of the unstable plaque, that finally determine the clinical surfacing of the disease [13-15].

Taking this into account, it is not unexpected that several biomarkers reflecting the inflammatory process have been associated to atherosclerotic disease and its progression [13-17]; unfortunately, inflammation is a common response to all pathogens, and the signals and mechanisms driving inflammatory response are not tissue-specific, nor are specific for any

inflammation-triggering agent, including oxidized LDL, i.e., the inflammatory trigger of atherosclerosis. Besides, inflammation is always a systemic response due to the endocrine action of cytokines; for these reasons the search for atherosclerotic inflammation markers has led to the identification of several indicators associated to increased risk of acute cardiac and cerebrovascular events, yet none specific.

Among those proposed, there are primary inflammatory markers such as cytokines, which trigger (TNF- α , IL-6) or modulate (IL-10) the whole inflammatory process, as well as secondary markers, e.g., adhesion molecules (CAM) whose expression in endothelial cells mediates the migration of inflammatory cells into the arterial wall, or the acute phase proteins such as serum amyloid A component (SAA), or C-reactive protein (CRP), or other proteins produced by activated macrophages such as the Pregnancy Associated Plasma Protein A (Figure 1).

At the moment, C-reactive protein is the most studied inflammation marker in the setting of atherosclerosis. CRP is a pentraxin produced by hepatocytes during inflammation, but is also produced by lipid-laden macrophages in atherosclerotic plaques, thus suggesting that slight but persistent elevation of serum CRP reflects the individual atheromatous burden. Besides, since CRP is an activator of the complement cascade, the finding that the complement membrane attack complex is activated inside the plaque suggests that the intra-plaque production of CRP sustains an auto-toxic mechanism which acts within the plaques promoting cell death and acute thrombotic events, thus linking plasma levels of CRP with key events on plaque progression [18]. Indeed, in line with these findings, CRP appears to be an independent predictor of acute cardiovascular events both in asymptomatic subjects [19, 20] and in patients with unstable angina [21]; moreover, elevated CRP levels are a predictor of a worse prognosis in ischemic stroke patients [22, 23].

As regards haemostatic markers, it should be taken in mind, as stated above, that many proteins involved in coagulation and fibrinolysis are acute phase reactants, i.e., proteins, such as fibrinogen, whose plasma levels increase during inflammation due to the effect of inflammatory cytokines on gene expression in hepatocytes; fibrinogen [24] and D-dimer [25] have been proposed as biomarkers of unstable plaque (Figure 1). While fibrinogen is produced in the liver under the stimulation of cytokines, the D-dimer derives from the hydrolysis of fibrin by plasmin, thus is a marker of the fibrinolytic processes and of thromboembolic events. D-dimer levels correlate also with blood levels of CRP and serum amyloid A (SAA) [25], thus it can also be considered as a marker of inflammation [26]. D-dimer levels in blood have also been associated with increased risk of cardiovascular events in asymptomatic subjects [23, 27], of ischemic and cardio-embolic stroke [28, 29]. A recent retrospective study evaluated the diagnostic value of the serum biochemical markers CRP, D-dimer and fibrinogen in differentiating etiological subtypes of ischemic stroke basing on the TOAST classification system. CRP and D-dimer levels were significantly different among the subtypes and were the highest in cardioembolism (CE), followed by large- and small-artery occlusion; no significant difference between the subtypes was found for fibrinogen. Thus the combined evaluation of CRP and D-dimer serum levels could be useful for identifying the etiological subtypes of acute ischemic stroke, especially for predicting CE (CRP > 6.96 mg/L and D-dimer > 791.30 ng/mL: sensitivity 65%, specificity of 91%) [30].

Inflammation has not only a role in the pathogenesis of atherosclerosis, i.e., a main cause of stroke, but also in the tissue response to ischemic or haemorrhagic damage; for this reason,

inflammatory biomarkers (notably the same biomarkers mentioned above) have a promising value in predicting the short term and long-term prognosis of stroke.

Figure 1. The diagram shows the main modifiable and non-modifiable risk factors as well as the pathophysiological sequence of plasma biomarkers corresponding to atherosclerotic plaque formation, progression and destabilization. 1. Endothelial activation: soluble forms of adhesion molecules may indicate the extent of endothelial cell activation (sICAM soluble intercellular adhesion molecule; sVCAM soluble vascular cell adhesion molecule, soluble E-selectin). 2. Inflammation: interleukin (IL-1; TNF- α ; IL-6; IL-8; IL-10), chemokine (MCP-1, monocyte chemotactic protein 1), and acute-phase reactants (fibrinogen; CRP, C-reactive protein; SSA, serum amyloid A; PAPP-A, pregnancy-associated plasma peptide A) are markers for basal inflammation that leads to development of atherosclerotic plaque. 3. Oxidative stress promotes LDL oxidation (LDLox), the development of foam cells and the progression of atheroma (MPO, myeloperoxidase; GGT, gamma-glutamyltransferase). 4. Plaque remodelling: inflammation promotes angiogenesis (VEGF, vascular endothelial growth factor; PlGF, placental growth factor; HGF, hepatocyte growth factor), activation of MMPs (matrix metalloproteinases, including MMP-1, -2, and -9), and release of PAPP-A (pregnancy-associated plasma peptide A) from macrophages. 5. Rupture and/or erosion of the unstable plaque leads to thrombosis and platelet activation (DD, D-dimer; sCD40L, soluble CD40 ligand; P-selectin).

In particular, if considering the short term prognosis, it is now clear that the exacerbation of the inflammatory response, which is substantiated by higher serum IL-6, CRP and SAA, is followed by increased in-hospital mortality for ischaemic stroke. If considering that inflammation is in itself a process aimed to destroy pathogens, rather than to protect the tissue, it is reasonable to suppose that the unbalanced action of anti- and pro-inflammatory cytokines enhances the potentially damaging side of inflammation, i.e., production of free radicals, microvascular damage, activation of proteases, chemotaxis of inflammatory cells; thus cytokines, the key players in the inflammatory mechanism, contribute to the progression of ischemic damage [31]. Microglia, astrocytes, endothelial cells, and neurons are the main cell types in the brain able to secrete pro-inflammatory and anti-inflammatory cytokines in

response to damaged tissue after ischemia [32], and notably not only the increased production of pro-inflammatory cytokines (TNF- α , interleukin (IL)-1 β , IL-6) is associated to worse prognosis, but the impaired production of anti-inflammatory cytokines (such as IL-10) is correlated with a larger infarct size in animal models and a possible worse clinical outcome in humans [33].

It is not yet clear whether the association between cytokine levels and the prognosis of stroke reflects a direct role of them in its clinical evolution, or it is only an epiphenomenon of the extent and severity of the nervous tissue damage; it should be taken in mind that the biological action of cytokines is not a direct consequence of their concentration in blood: in fact the biological action of the main cytokines, such as IL-1 and TNF- α is finely tuned by the combined effects of several ligands and receptors, that make difficult to establish a direct relationship between the plasma concentration of each cytokine with its real biological action at tissue level. A better understanding of this key aspect of brain damage is needed to allow a clinical application of this promising research line, which to now has produced partially conflicting findings when using cytokine serum levels for predicting outcome and infarct size [31].

OXIDATIVE STRESS AS A POSSIBLE SOURCE OF BIOMARKERS

Oxidative stress plays a key role in the aetiopathogenesis and in the modulation of the inflammatory process; in fact, many reactive oxygen species (ROS) are produced by inflammatory cells as mediators of the inflammation processes. Oxidative stress is also involved in the genesis of plaque, as ROS contribute to the oxidation of low-density lipoproteins (LDL), which, in turn, trigger the inflammation within the vessel wall (Figure 1) [2, 34].

The oxidation of LDL was highlighted by earlier studies as the single crucial event in pathogenesis of atherosclerosis, with special reference to the initiation of the lesions [2]. Subsequent research has shown however that the implication of oxidative processes in atherosclerosis may be considerably wider, including effects on several other important pathological changes occurring in the diseased vessel wall. Redox reactions are in fact involved in stimulation of smooth muscle cell proliferation, contributing to lesion thickening and expansion. Besides, the activities of matrix metalloproteinases and of their inhibitors, major determinants of plaque stability, are modulated through redox changes in critical portions of their protein structure. Some aspects of endothelial dysfunction (e.g., impairment of nitric oxide production, expression patterns and levels of adhesion molecules) are also affected by oxidative events, and several other redox-sensitive steps are present in signal transduction, apoptotic cell death and platelet functions. Altogether, current experimental studies consistently indicate that redox processes may contribute to turn a mildly stenotic, silent plaque into a vulnerable, symptomatic and potentially fatal lesion. A series of enzyme activities, found in cellular elements present in the lesions (endothelial cells, phagocytes, smooth muscle cells, fibroblasts) have been proposed as sources of the oxidants involved; these include NADPH-oxidases, NO-synthase, xanthine oxidase, myeloperoxidase, lipoxygenases and enzymes of mitochondrial respiration.

Since 1995, growing attention is dedicated to γ -glutamyltransferase (GGT) [35] whose levels in serum have been recently come on stage as a novel marker for cardiovascular prognosis related to atherosclerosis. The potential role of GGT in the pathogenesis of atherosclerosis is independently suggested by the biochemical demonstration of the production of free radical and reactive oxygen species as a by-product of GGT activity, but also by epidemiological and histochemical studies.

SERUM GAMMA-GLUTAMYLTRANSFERASE: A PROGNOSTIC MARKER IN CARDIO - VASCULAR DISEASES

The determination of serum or plasma levels of GGT is one of the basic biochemical tools for evaluation of liver function. The activity of GGT in blood is a sensitive biomarker of liver disease. As such, serum GGT activity is the parameter of choice for monitoring alcohol abuse and its association with morbidity was initially reported in this perspective [36].

Conigrave and collaborators [37] were the first to appreciate that GGT has a predictive value irrespective of hepatic disease or alcohol consumption. With respect to atherosclerotic diseases, it was observed that serum GGT levels were positively associated with increased risk of myocardial infarction [38] and more recently, the association between serum GGT and the risk of stroke was also observed [39-42].

These associations are partly explained by the known correlations between serum GGT levels and known cardiovascular risk factors, such as changes in blood lipid [39], body mass index [43], hypertension [44], glucose intolerance [45], insulin resistance [46] and type 2 diabetes [47]. GGT levels also correlate positively with novel risk factors such as C-reactive protein, fibrinogen and F2-isoprostanes [48]. It is worth emphasizing that most of the studies mentioned above refer to serum GGT values within the laboratory reference range, which would not otherwise raise specific health concern.

Of particular interest, the study by Wannamethee and collaborators [38] focused the relationship between GGT and ischemic heart disease (IHD). In a large prospective study (7613 middle-aged men, with a 11-years follow-up), GGT levels in the normal range were strongly associated with all-cause mortality, and the association was largely due to a significant increase in deaths from ischemic heart disease in the top quintile of GGT distribution. Serum GGT was positively correlated with pre-existing ischemic heart disease, diabetes mellitus, antihypertensive medication, systolic and diastolic blood pressure, total and HDL cholesterol, heart rate and blood glucose, while a negative association was found with physical activity and lung function. After adjustment for these variables, elevated GGT (highest quintile, ≥ 24 U/l, vs. the rest) was still associated with a significant increase in mortality from all causes and from IHD. The increased risk of IHD mortality was more marked for patients with evidence of ischemic heart disease at screening, particularly those with previous myocardial infarction; these findings clearly pointed to a connection of GGT with underlying atherosclerotic coronary artery disease.

The supposed connection of GGT with atherosclerotic disease has received a detailed assessment in a prospective study of Emdin and collaborators [49]. The study included a six-year follow-up of 469 patients with ischemic syndrome and angiographically documented coronary artery disease (CAD). After correction for other cardiovascular disease risk factors

(age, smoking, serum cholesterol, left ventricular ejection fraction, body mass index, diabetes mellitus), or confounding factors (serum alanine aminotransferase, self-reported alcohol consumption), the prognostic value of serum GGT activity for cardiac death and non-fatal infarction was confirmed. In particular, the significance of serum GGT was more evident in a subset of patients prone to plaque complications, i.e., characterized by the association of diffuse atherosclerosis (“multivessel disease”) and a history of previous myocardial infarction (approx. 36% of the whole population). The risk was increasing using two different GGT cut-off values (25 or 40 U/L, both considered within the normal range), and the event excess was concentrated within the first three years. The prognostic significance of serum GGT was thus correlated with the diffusion of coronary artery disease. Interestingly, the significance of serum GGT appeared to depend on the instability of plaque as well, as indicated by the fact that the prognostic value of GGT disappeared after revascularization by angioplasty, i.e., a procedure causing plaque stabilization [50]. Thus, the unfavourable prognosis signalled by elevated serum GGT seems to apply specifically to patients with vulnerable plaques, suggesting that connections of some kind must exist between GGT and the processes involved in plaque instability. Moreover, GGT, CRP and fasting glucose show an additive prognostic value; in fact, high levels of these biomarkers identify a subset of patients with the highest risk of vascular events [51].

The study by Ruttman and collaborators [52], carried out in as many as 163,944 Austrian adult subjects, has now rather conclusively shown that serum GGT levels are an independent prognostic factors for fatal events of chronic forms of CAD, congestive heart failure and ischemic or haemorrhagic stroke. The finding was found to be true for both-sexes, with a clear dose-response relationship and a stronger significance as far as younger subjects were concerned. Ruttman and colleagues established the prognostic value of GGT for cardiovascular events at serum levels that lie within normal values. The receiver operating characteristics analysis suggested GGT cut-off values of 15.5 U/L for men and 10.5 U/L for women, corresponding to 27.6 U/L and 18.7 U/L, respectively, for current measurements made at 37°C.

In the last year other prospective studies, included the Framingham heart study [53-55], and meta-analysis confirmed the association between GGT and cardiovascular [56] or cerebrovascular disease [42] related to atherosclerosis.

GAMMA-GLUTAMYLTRANSFERASE INSIDE PLAQUES: POSSIBLE CONNECTIONS WITH SERUM GGT

Epidemiological studies suggest a relationship between circulating GGT and the evolution of atherosclerotic plaque, but the pathogenetic mechanism has not been elucidated yet. A clue was independently provided by studies showing the presence of GGT inside atherosclerotic lesions. Histochemical studies, in fact, revealed intense GGT activity in the intimal layers of human atherosclerotic lesions, apparently localised in CD68+ macrophage-derived foam cells [57, 58]. GGT-positive cells were found to co-localise also with immunoreactive oxidized LDL [59], and catalytically active GGT could also be detected in micro-thrombi adhering to the surface of atheromas [60].

GGT catalyses the first step of extracellular glutathione (GSH) degradation, i.e., the hydrolysis of the gamma-glutamyl bond existing between glutamic acid and cysteine, in this way GGT allows to use extracellular GSH as a source of cysteine and amino acids for the synthesis of intracellular GSH [61]. In pathological conditions, these reactions may have important pro-oxidant implications [62]. In fact, cysteinyl-glycine, the dipeptide that originates from hydrolysis of GSH, is extremely efficient in transferring electrons to metal cations, thus triggering a redox cycling capable to catalyse the production of free radicals and ROS [62, 63]. These reactions have been shown to take place inside plaques, thus GGT activity might contribute directly to the oxidative events influencing plaque evolution and rupture. This hypothesis was confirmed by the finding that morphologically unstable plaques contain more GGT activity [64].

In order to understand the precise role of the GGT in plaque instability, it is necessary to understand how serum GGT levels reflected GGT activity and function within the plaque. The origin of GGT activity detected in atherosclerotic plaques is still unclear. A possible source is represented by macrophages; in fact, it has been shown that GGT is over-expressed and released by the pro-inflammatory M1 macrophages [65] present in the active plaques. Anyway, the correlation between GGT activity found within plaques and in serum suggests also an exchange of GGT activity between the two compartments [64]. Another line of evidence points to the possibility that the source of serum GGT may be identified in circulating platelets, as the two parameters are usually correlated. Thus, it has been proposed that the increased GGT levels observed in atherosclerotic patients may originate from increased platelet consumption at the site of plaques [66]. A recent report, pointing to a prognostic value of elevated serum GGT in stent restenosis, in fact appears to support the potential role of platelets as a source of circulating GGT [67].

GGT in blood is carried in macromolecular complexes (fractions) whose chemical and physical properties have partially been defined [68]. Four GGT fractions have been detected in plasma of all healthy subjects by size exclusion chromatography [69]: b-GGT (2000 kDa), m-GGT (940 kDa), s-GGT (140 kDa) and f-GGT (70 kDa). In healthy subjects, only b-GGT levels are clearly associated with the main cardiovascular risk factors (i.e., body mass index, systolic blood pressure, serum glucose, serum cholesterol, serum triglycerides) as well as with inflammatory biomarkers (leukocyte count, C reactive protein) at difference with other fractions, and in particular f-GGT, the main fraction found in healthy individuals [70]. Furthermore, only b-GGT was found in human atherosclerotic plaques, co-localized with products deriving from the pro-oxidant reactions catalysed by GGT activity, thus suggesting that only this fraction, rather than total GGT itself, may be responsible of the association between GGT [64] levels and atherosclerotic disease. Besides, in a group of patients subjected to carotid endoarterectomy, a significant correlation was found between serum and intra-plaque b-GGT activity [64].

The physical features of the molecular complex corresponding to b-GGT are those of membrane microvesicles, likely microparticles and/or exosomes; this finding opens new perspectives on the role of serum GGT on atherosclerotic-related events [68].

Microparticles are nowadays considered main characters in cell communication as well as in the modulation of inflammation and haemostatic balance; microparticles expose tissue factor and phosphatidylserine that confer the pro-coagulant properties to microparticles [71]. Several studies have documented increased platelet, leukocyte or endothelial-derived microparticles in patients with cardiovascular disease [72]. Further prospective studies will

clarify the prognostic value of pro-coagulant microparticles in the prediction of thrombotic events. A challenging question is whether microparticles can be used as a marker of the haemostatic balance of blood that would be of help to identify “vulnerable” patients. In fact, the consequences of plaque rupture depend both on the solid state of the atheroma and the “fluid” phase of the blood that can predispose toward coronary thrombosis.

Future studies will clarify if serum b-GGT activity represent a marker of the atherosclerotic burden, suggesting the presence of a vulnerable plaque, or of the blood coagulant activity, thus indicating a vulnerable patient.

ABSTRACT

Stroke may represent the clinical expression of several inherited disorders, including the mitochondrial disease Mitochondrial Encephalomyopathy, Lactic Acidosis and stroke-like episodes (MELAS). Moreover, converging evidences link together inherited or acquired mitochondrial dysfunction and stroke, and provide intriguing therapeutic implications in terms of neuroprotection.

Here we revise the available knowledge linking together inherited and acquired mitochondrial dysfunction and stroke.

Keywords: stroke, genetics, mitochondrial disease, mtDNA, MELAS

INTRODUCTION

Multiple evidences suggest that the etiopathogenetic mechanisms of stroke have not been fully understood; the conventional vascular risk factors, however, do not entirely account for the incidence of stroke in unexposed populations, and more than one-fourth of cases, particularly strokes in young patients, are classified as cryptogenic [1]. Consistently, twin and family history studies suggest a role for genetic factors in stroke risk that could be

* Corresponding Author G. Siciliano Department of Clinical and Experimental Medicine, Neurological Clinic, University of Pisa, Via Roma 67, 56100 Pisa, Italy, Email: g.siciliano@med.unipi.it.

particularly relevant especially in young patients and non-cardioembolic ischemic stroke [2, 3]. A full review of the stroke associated genetic disorders goes beyond the scope of this chapter, and has already been treated also by our group [4]. Instead, we want to focus our attention on the emerging evidence linking together inherited and acquired mitochondrial dysfunction and stroke.

WHY MITOCHONDRION?

According with the WHO definition, stroke is a cerebrovascular accident caused by “the interruption of the blood supply to the brain (...). This cuts off the supply of oxygen and nutrients, causing damage to the brain tissue.” In order to fully understand the axiom, we have to enter into the physiological and ultrastructural mechanisms of stroke pathogenesis. Since the sudden interruption of oxygen and oxidizable substrates first impairs the ability to meet the high energy demand of neuronal cells, it is therefore appropriate to analyze the main source of cellular energy, the mitochondria. Although the Central Nervous System (CNS) represents only 1-2% of the body weight, it receives, in basal conditions, approximately 15% of the cardiac output; therefore, the cerebral blood flow is typically 750-1000 millilitres per minute. The complex and delicate balance of the biochemical and electrophysiological networks that underlie neuro-neuronal and neuro-glial connections are based on the chemical energy burst from the phospho-derivate products of anaerobic and, mostly, aerobic glucose metabolism. A peculiar feature of neuronal cells, the excitability, requires correctly functioning membrane wall Na^+/K^+ ATPase pumps, intracellular Ca^{2+} -concentration regulation, intra and extra-cellular signaling molecules, vesicles transporting, and cellular differentiation [5, 6].

This background clearly suggests a pivotal role of the mitochondria on CNS functions, as demonstrated in different disease models [7, 8, 9]. Indeed, the mitochondrion is currently known to play a major etiopathogenetic role in many human diseases and processes: neuromuscular and neurodegenerative disorders (i.e., Parkinson’s and Alzheimer’s diseases), diabetes mellitus, aging, programmed cell death and carcinogenesis, to name a few [5, 10, 11, 12, 13].

OVERVIEW OF MITOCHONDRIAL BIOLOGY AND GENETICS

More than a billion years ago, aerobic bacteria colonized primordial eukaryotic cells that were not able to use oxygen. This symbiotic relationship could soon become permanent as bacteria evolved into mitochondria, providing aerobic metabolism to host cells. Mitochondria are ubiquitous in eukaryotes and are essential for their survival, representing the cellular powerhouse that generates ATP, a chemical energy source, through a chain of reactions known as oxidative phosphorylation (OXPHOS) [5, 10].

Mitochondria are surrounded by two distinct membranes, an outer (OMM) and an inner membrane (IMM) that invaginates to form the “cristae”. The mitochondria form complex networks by virtue of their ability to move, fuse, and split. There are tissue-specific differences in mitochondrial activity and biogenesis, mainly related to the tissue dependence upon oxidative phosphorylation for energy provision: neurons, cardiac and skeletal muscles

have high mitochondria density that explains their vulnerability to energy-dependent defects and injuries resulting from mitochondrial dysfunction.

Human mitochondrial DNA (mtDNA) is a small circular, double-stranded molecule of 16,569-kb, which contains 37 genes: 2 rRNA genes, 22 tRNA genes, and 13 structural genes encoding subunits of the mitochondrial respiratory chain, the ‘gas station’ of oxidative metabolism, where ATP is synthesized [10, 12, 13, 14]. Reducing equivalents from the Krebs cycle and the β -oxidation spirals are passed through several protein complexes (the electron transport chain –ETC–) embedded in the IMM, and consisting of four multimeric complexes (I to IV) plus two small electron carriers, coenzyme Q and cytochrome c. The energy generated by the reactions of the ETC is used to pump protons from the mitochondrial matrix into the space between the mitochondrial membranes, in order to maintain an electrochemical proton gradient, that is used by complex V (the ATP synthase) to generate ATP as protons flow back into the matrix through its membrane-embedded F₀ portion, the “rotor” of the turbine [12, 14].

Mitochondria descend exclusively from the oocyte; therefore, mtDNA is maternally-inherited. Cells have variable amount of mitochondria, each of which contains multiple (polyplasmcy) and identical (homoplasmy) copies of mtDNA. Mutations in all the mtDNAs are defined homoplasmic. Differently, heteroplasmic mutations, which are harboured by only a part of mtDNA molecules, are often responsible for disease phenotypes [12, 14]. Molecules of mutated and wild-type mtDNA coexist in the same cell and the mutant genomes are randomly distributed to the daughter cells; therefore, their amount is different in the various mitotic cycles (different mitotic segregation). Symptoms will appear when the mutated molecules will be enough to cause energetic crisis (threshold effect), and it’s worth to consider that the percentage of mutated genomes able to manifest a phenotype varies in different tissues. Age of onset and clinical picture will depend on the amount of mutated genomes and on their distribution in the different tissues. Tissues particularly dependent on oxidative metabolism, and/or characterized by a low mitotic rate (i.e., skeletal and cardiac muscles, central nervous system, liver and kidney) appear more vulnerable to alterations of the mitochondrial function; therefore, a relatively small amount of mutated genome may be sufficient to cause phenotype.

Beyond energy metabolism, mitochondria are also involved in iron-sulfur cluster assembly, intracellular Ca²⁺ concentration, ROS signaling, apoptosis, immunity and neuronal plasticity [15, 16].

MITOCHONDRIAL DISEASE

Clinically, the most important consequence of mitochondrial genetic complexity is the extreme heterogeneity of the phenotypes associated with mitochondrial defects.

The same genetic defect may result in different clinical pictures, also within the same family and, by contrast, similar phenotypes may be the expression of different mutations (either nuclear or mitochondrial). Moreover, phenotypes are extremely polymorphous, and may range from pure myopathies to multisystem disorders, making difficult to draw definite genotype/phenotype correlations.

At the molecular level, mitochondrial encephalomyopathies are classified as those due to mutations in mtDNA, which cause maternally inherited or sporadic disorders, and those due to mutations in nuclear DNA (nDNA), Mendelian inherited. A more practical framework for categorizing these diseases distinguishes three groups: mtDNA defects; nDNA defects that directly or indirectly affect the respiratory chain; defects of mtDNA maintenance (impaired intergenomic communication) [17]. Aim of this work is not to provide a comprehensive revision of the different clinical manifestations of mitochondrial diseases, already revised elsewhere [17]. We here focus our attention on the mitochondrial stroke-like disease, the MELAS syndrome.

MELAS, A CEREBROVASCULAR MITOCHONDRIOPATHY

Mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes (MELAS) (OMIM 540000), is a multisystem disorder with a clinical onset usually in the first two decades of life. It consists of a progressive encephalomyopathy characterized by repeated stroke-like events (SLE) mainly involving posterior cerebral areas. Typically, the SLE are characterized by the acute onset of neurological dysfunction without a corresponding classical vascular distribution, being the irregular distribution more consistent with a metabolic endothelial dysfunction of small vessels [17]. The single episode may lead to reversible aphasia, hemianopia, cortical blindness, but accumulating irreversible neurological deficit and radiological burden become prominent; in fact, the cumulative residual effect of SLE results in impaired motor abilities, vision and cognition. CNS areas typically involved are, asymmetrically, temporal, parietal or occipital lobes, whereas deep white matter is relatively spared. Diffusion-weighted (DWI) MR-sequences are the gold standard imaging techniques for the characterization of these infarct-like metabolic lesions. Although SLE typically involve small vessels, some reports suggest a role in large vessel occlusion by thrombus formation in an abnormal endothelium or arterial dissection (very rare). The pathogenetic mechanisms leading to SLE are yet not fully understood, and two main hypotheses are being considered: (i) the neuronopathy hypothesis: impaired OXPHOS results in high potassium and glutamate in the synaptic cleft, and the consequent neuronal hyperexcitability may clinically manifest with SLE, seizures or migraine; (ii) the angiopathy hypothesis: histological analysis in MELAS revealed increased enlarged mitochondria with complicate cristae in pericytes of capillaries, endothelial cells and smooth muscle cells of pial vessels and small intracerebral arteries [19, 20]. This pathological data may represent a compensatory mechanism to overcome the OXPHOS defect, and SLE may thus occur when this compensatory reaction does not meet the increasing demand of a brain region. Impaired vasodilatory mechanisms (a feature of small vessels dysfunction) have been reported in MELAS patients. Finally, changes in the nitric oxide (NO) pathway have been linked to SLE presentation and justify the use of L-arginine (a NO precursor) therapy during the acute metabolic crises in MELAS [21, 22, 23].

Recurrent migraine-like headaches and vomiting, exercise intolerance, seizures, ataxia, cardiomyopathy, sensorineural hearing loss, short stature and lactic acidosis are other frequent clinical features [1, 24]. The Italian Network of Mitochondrial Diseases has recently demonstrated that SLE in MELAS are tightly associated with lactate acidosis, generalized seizures, cognitive impairment, and hearing loss [18]; interestingly, a potential gender effect

has been postulated in this study [18]. In the Italian cohort, we observed that MELAS group related to the 3243A>G mutation in mtDNA was enriched in males compared with the non-MELAS group ($p = 0.019$); this observation was not explained by other possible confounding factors such as age of onset, age at the last control, disease duration, levels of heteroplasmy in tissues (muscle, blood and urine), that were not significantly different between the two groups. Even if this finding need to be confirmed through specifically designed longitudinal studies, gender effect is not a novel concept in mitochondrial diseases. An higher prevalence of Leber hereditary optic neuropathy in males is already known [25], and may be related to multilayer cytoprotective effects induced by estrogens [25].

A number of point mutations have been described in association with MELAS phenotype. Although some of them are located in polypeptide-encoding genes, especially ND (NADH dehydrogenase, Complex I), they more frequently arise in tRNA genes. The most commonly reported mutations associated with MELAS are the m.3243A>G and m.3271T>C in tRNA Leu (UUR) [17]. Multiple additional mutations may also cause MELAS [26].

The diagnosis of MELAS should be kept in mind when the following features are present: (i) stroke-like episodes which start typically before age 40, (ii) seizures, cognitive impairment or both and (iii) mitochondrial dysfunction as showed by the presence of lactic acidosis, ragged-red fibers or both. Conventional MRI and proton spectroscopy are important and may detect a lactate peak in both brain and CSF (cerebro spinal fluid), supporting a clinical suspect of mitochondrial disorder [27]. Molecular diagnosis is then necessary to confirm the clinical suspect of MELAS. Heteroplasmy levels of the m.3243A>G mutation are usually higher in muscle and urine than blood [18]. Therefore, urine sediment is a valid and easily accessible tissue for the detection of the m.3243A>G mitochondrial mutation.

THE VASCULAR CASCADE LEADING TO ISCHEMIA/REPERFUSION INJURY DURING ACUTE STROKE IS LINKED TO THE MITOCHONDRION: THE ROS STRATEGY AND THE OXYGEN PARADOX

So far, we focused our attention on inheritable mitochondrial diseases; however, and not surprisingly, growing evidences suggest that specific mitochondrial haplogroups, mitochondrial distribution, SNPs (Single Nucleotide Polymorphisms) variability, and de-novo aging-related mtDNA mutations/amplifications may influence risk, prognosis, and also the therapeutic response in acute or chronic CNS diseases, including stroke [7]. Cellular stress response consists in an “evolutionarily conserved mechanism” that activates molecular homeostatic-inflammatory pathways after exogenous and/or endogenous injuries [5, 28]. Cellular energetics, mitochondrial energy production and oxidative stress are crucial for cell stress adaptation and cell response; therefore, variable mitochondrial function, secondary to different genetic background, would differentially modulate the organism’s response to different injuries. Mitochondria are, in fact, dynamic organelles, and both function and morphology may vary within cellular type, developmental stage, and environment [29, 30]. Moreover, mtDNA appears more susceptible than nDNA to oxidative stress and environmental toxins [31] and it replicates continuously, independently from the cell cycle

[32]. During lifetime mitochondria may thus accumulate aging/environment related mutation(s) that, in turn, may lead to energy failure, ROS production and cell damage [33].

Mitochondrial function and ROS-homeostasis are paramount for vascular cell remodeling (proliferation and apoptosis), inflammatory response and atherosclerosis [5, 34, 35, 36, 37] and may favour atherosclerotic plaque rupture [38].

Given its high metabolic rate, brain appears particularly vulnerable to the deleterious effects of ischemia. The cessation of blood supply leads to ischemia and eventually cell injury by decreased availability of oxygen and other nutrients (first-direct ischemia hit). Ischemic injury results from severe impairment of cell metabolism through decreased ATP availability, subsequent loss of membrane potential, and calcium overload that leads to cell death through either necrosis, apoptosis or autophagy. During ischemia, loss of mitochondrial membrane potential and functional impairment of mitochondrial proteins have been observed, leading to cessation of oxidative phosphorylation and accumulation of ROS (reactive oxygen species), suggesting a pivotal role of mitochondria in the pathophysiology of ischemic injury [39, 40].

Restoration of blood flow after a sufficiently prolonged ischemia may result into further injury, as a result of early and delayed reperfusion injury; therefore, rather than an expected decrease of the injured zone, a larger zone may be observed (second-indirect ischemia hit).

In early reperfusion injury, oxygen may exacerbate brain damage through multiple mechanisms, such as activation and modulation of similar-apoptotic and necrotic pathways, overproduction of inflammatory mediators, stimulation of leucocyte diapedesis, and alteration of enzyme conformations. In this regard, mitochondrial proteins appear particularly vulnerable, and further mitochondrial damage may result in further ROS production and overwhelming stimulation of apoptosis and necrosis, in a vicious manner [40]. Delayed-reperfusion injury is instead related to the promotion of tissutal and vascular remodeling processes that finally result in tissue fibrosis and scar formation.

All these issues may be related to repeated bursts of ROS production that may be observed during cessation and subsequent recovery of oxygen delivery (ischemia/reperfusion -I/R- and post-reperfusion phases of I/R injury). The biochemical, pathological, and clinical consequences of this “oxygen paradox” are related to the type and amount of ROS, as well as the location in the cell, both for early and delayed reperfusion injury (ROS-related angiogenesis and cell division and differentiation regulation) [40]. A limited and circumscribed ROS production leads to less severe ischemic injury, whereas massive ROS production that involves all mitochondria may result in massive ischemic injury [40].

It is well known that mitochondrial respiratory chain complex I-III impairment is linked with I/R damage [39]. Moreover, deglutathione complex II and phosphorylated complex IV have been proposed as relevant sources of ROS. ROS induced ROS-formation in post-ischemic phase by the Krebs enzymes and NADPH oxidase (NOX) activation is suggested by in vivo models reporting decreased glial activation and neuronal cell degeneration following NOX modulation. Nox4 represents the most expressed isoform of NOX in brain tissue and its modulation by hypoxia related responses may not only influence the redox set point at cellular level, but also play a role in cell proliferation and differentiation during the later reperfusion phases [39, 40].

A pivotal role in the balance of the opposite tissue responses to O₂ delivery interruption/recovery has been proposed for mitochondria permeability transition pores (mPTPs): their short-term opening has been involved in cardioprotection (transient ROS formation), whereas long-lasting opening may irreversibly impair cellular homeostasis [41].

Growing evidence suggests that sub-ischemic damage may precondition brain tissue through the activation of specific cell surviving programs, and modulation of key enzymes involved in cellular death pathways. Ischemic injuries not reaching the “necrotic threshold” may thus result in brain protecting responses. Again, mitochondria and, specifically, ROS are well known leading actors in the pathways involved in these processes, and may play a crucial role in the balance between cell injury and protection from ischemic damage [40, 42].

TARGETING MITOCHONDRIA FOR STROKE THERAPY. PRECLINICAL STUDIES

Although extensive studies have shown that several neuroprotectants reduce infarction and improve neurological functioning in animal models of stroke, few of those agents have been successfully translated into clinical practice. This situation necessitates the exploration of novel neuroprotectants, such as ischemia postconditioning. Ischemic postconditioning initially refers to a series of brief ischemia and reperfusion cycles applied after reperfusion, which is a concept defined in contrast with ischemic preconditioning. While postconditioning is performed after reperfusion, preconditioning is conducted before the onset of ischemia [43]. In stroke research, the methods used for postconditioning include a stuttering reperfusion, meaning a series of intermittent hypoxia, a single period of ischemia or hypoxia. Cellular pathways involved in postconditioning converge to a common target, the mitochondrion, and a particular role may be played by ATP-dependent potassium channels, ROS, and mPTPs [44]. From the bench to the bedside, as reperfusion could paradoxically increase injury and tissue loss, mitochondrial-targeted ischemic postconditioning may potentially present significant implications for stroke management, in terms of decreased infarct volume, and better neurological outcome.

An early administered mitochondria targeted therapy may therefore support and eventually enhance the effectiveness of standard stroke treatments. Supporting energy production may have a positive impact on reducing damage caused by a stroke and may favour a good functional recovery.

Data from preclinical studies emphasize the importance of mitochondria as candidates for stroke neuroprotection, since mitochondrial metabolism enhancers have been related to better preserved penumbral tissues [45]. Up-regulation of ATP synthesis by purinergic receptor stimulation has been proved to be a possible strategy: binding of 2-methylthioadenosine diphosphate trisodium salt (2meSADP) to purinergic receptor P2Y₁R activates the inositol triphosphate (IP₃) cascade resulting in release of calcium (Ca²⁺) from endoplasmic stores of astrocytes, translating into increased ATP production within the mitochondria for the increased cellular demands following injury and neuroprotection [46]. This molecules enhance neuronal survival, reverse the beading and swelling of dendrites associated with neuronal death, repolarize mitochondrial membrane potential [47] and reduce lesion volume in a cerebral ischemia/reperfusion model (middle cerebral artery occlusion –MCAO- with 60 min reperfusion in rats [45]).

Furthermore, methylene blue (an alternative electron carrier shuttling electrons between NADH and cytochrome c) revealed to be effective in attenuating I/R syndrome [48], and

protective in a transient cerebral ischemia model using the intraluminal filament MCAO in rats [49].

GENETIC MITOCHONDRIAL VARIATION AND STROKE SUSCEPTIBILITY

Over the past years a growing interest on the correlation between common mitochondrial genetic variations (SNPs) and haplogroups and stroke risk (or stroke phenotypes) have been reported.

Mitochondrial haplogroups are common genetic polymorphisms within the mitochondrial genome, accumulated over time, that describe classes of continent-specific genotypes, evolved from the same ancestor, which can be detected by restriction fragment length polymorphism (RFLP) analysis. It has been supposed that these genetic polymorphisms might lead to impaired energy generation and to increased amount of ROS, causing subtle differences in the encoded proteins and, thus, minimum changes in mitochondrial OXPHOS activity and free radical overproduction [50].

Previous evidences show that these genetic variability may influence the penetrance of mitochondrial genetic disorders, longevity, cancer, fertility, diabetes, hypertension, neurodegenerative diseases, but also cardio and cerebrovascular diseases, with a complex interaction between classical risk factors and genetic influences [51, 52, 53, 54, 55, 38, 13].

Studies on the role of mitochondrial haplogroups in stroke have produced conflicting results, although the trend seems to confirm an involvement of these variants as predictors of both clinical outcome and treatment response.

Two elegant studies carried out by Anderson and colleagues [56, 57] matched together autosomal and mitochondrial OXPHOS SNPs and stroke risk through a stroke genetic risk score. Interestingly, common mitochondrial genetic variants or multiple rare variants may interact to increase over-life stroke risk and white matter hyperintensity volume [56]. Moreover, an association between common genetic variants in OXPHOS genes and small vessel ischemic and hemorrhagic stroke has been demonstrated [57].

Biffi and colleagues [58] applied the same stroke genetic risk score demonstrating significant associations between common OXPHOS DNA sequence variants and clinical and radiographic markers of Alzheimer's Disease (AD), suggesting an overlapping genetic architecture between small vessel stroke and AD [58].

Specific haplogroups have also been found to be stroke-correlated. Majamaa and colleagues reported haplogroup U as a risk factor for occipital stroke in patients with migraine, in whom the mtDNA m.3243A>G mutation has previously been excluded [59]. In a Japanese study performed on 1081 patients in 2007, Nishigaki demonstrated an association between haplogroups A and atherothrombotic cerebral infarction in women, but not in men [60]. Some specific haplotypes seem also to play a protective role: in a Portuguese study on 534 ischemic stroke patients and 499 controls, haplogroup H1 was found to be significantly less frequent in stroke patients compared with controls [38]; similar results were observed for haplogroup D4 in a Chinese population [61]. Finally, Chinnery and co-authors demonstrated the protective role of sub-haplogroup K for both transient ischaemic attack (TIA) and ischaemic stroke, but not for coronary ischaemic vascular events [62].

However, a recent study on 9254 individuals from the Danish general population did not revealed an association of any mitochondrial haplogroups with risk of ischemic cardiovascular events [55].

For the geographical mtDNA characteristics, these conflicting results may be due to methodological issues, such as differences in study design, and in the descent of study populations.

A recently published study focuses on the possible impact of mtDNA haplogroups on short-term outcomes of neurological functions. 303 Chinese patients were investigated for changes between baseline and 14-day follow-up stroke severity, according to the National Institutes of Health Stroke Scale and the modified Rankin Scale scores, adjusting for age, hypertension, diabetes mellitus, TOAST subtype, antihypertensive treatment, glucose and cholesterol-lowering treatment. The Authors found that haplogroup N9 was an independent protective factor against neurological worsening [63].

CONCLUSION

Current treatment of stroke is focused to quickly restore blood flow to the damaged brain area, although this not only cannot be sufficient to restore normal neuronal functions, but may also result in worse functional outcomes. Converging evidence highlights the mitochondrial involvement in vascular diseases, focusing on several mito-footprints in the ischemic/reperfusion damage pathway. Mitochondrial involvement has been proposed in the pathophysiology of acute stroke, but the exact role for the mitochondrion and the mtDNA has not been comprehensively studied. Population-based analysis, as well as cell and animal models, have demonstrated that mitochondria may represent a potential target in stroke prevention and treatment, and also in post-stroke neurological recovery.

As the founder of the scientific method claimed more than 400 years ago the key must be sought in “this great book which stands continually open to our eyes (I mean the universe),” stroke researchers should analyze what already exists standing continually open to their eyes: the mitochondrion and the complexity of its machinery.

ABSTRACT

Cervical artery dissection (CeAD) is a major cause of ischemic stroke in young and middle-aged adults, but the incidence in the general population is low. While non-invasive methods for diagnosing CeAD have been substantially improved in the past two decades, the mechanisms of this potentially severe condition remains incompletely understood. Moreover, evidence based therapeutic strategies are lacking. Interestingly, in the past few years large international collaborative projects provided important novel information on environmental and genetic risk factors of CeAD, and led to new insight on the link between CeAD and other vascular diseases. Recently, the first phase 2 randomized trial of CeAD comparing antiplatelet agents to anticoagulants was published. This review aims primarily at summarizing novel findings regarding risk factors and treatment of CeAD.

Keywords: cervical artery dissection, ischemic stroke

INTRODUCTION

Cervical artery dissection (CeAD), caused by a hematoma in the wall of the cervical portion of an internal carotid or vertebral artery, and is a major etiology of ischemic stroke in young and middle-aged adults [1-3]. The incidence of the disease is relatively low in the general population, estimated around 3/100,000 inhabitants per year [4, 5]. The mean age of occurrence of CeAD is 44 years. Carotid dissections are more common than vertebral dissections in populations of European origin [5], while a predominance of vertebral dissection has been described in Asian cohorts [6, 7]. A slight male predominance was reported in European (but not North-American) cohorts, and is more marked in Asian populations [1, 8]. Men more often suffer from carotid dissection and are on average 5 years older than women at the age of CeAD occurrence [1, 9, 10].

In published series about 67-77% of CeAD patients suffer from ischemic stroke or transient ischemic attack, which may be an overestimation, since large CeAD cohorts were recruited through departments of neurology specialized in stroke care [1]. Other ischemic manifestations include retinal ischemia in case of carotid dissection and seldom spinal cord ischemia in patients with vertebral artery dissection. Cervical pain and headache are the most common symptoms, and may precede the onset of cerebral ischemia by days or sometimes weeks. Horner syndrome can occur in patients with carotid dissection, due to compression of sympathetic fibers by the enlarged artery. Other complications include tinnitus, cranial nerve palsy and, seldom, subarachnoid hemorrhage (mostly when the dissection extends intracranially).

Radiologically, pathognomonic signs of CeAD include the presence of a mural hematoma (best seen as a crescent-shaped hyperintensity on T1-weighted axial magnetic resonance images), or more seldom a double lumen, or an intimal flap. On angiography - now mostly magnetic resonance or computed tomography angiography - CeAD most often presents as a long, irregular stenosis. CeAD can also present as an arterial occlusion or a dissecting aneurysm. In patients with arterial occlusion, if a mural hematoma cannot be seen, the diagnosis of CeAD can only be confirmed if during follow-up the occlusion recanalizes and leads to a typical stenosis or a dissecting aneurysm. In ~15% of the cases, CeAD affects multiple arteries.

Although the pathophysiology of CeAD is incompletely understood, data from large hospital-based cohorts of CeAD patients have provided new insight into the environmental [11], and more recently the genetic risk factors of CeAD [12]. Moreover, while evidence-based data for the management of CeAD is scarce, the first randomized feasibility trial comparing antiplatelet agents to anticoagulants in patients with CeAD was recently published [13]. We will summarize the main new findings emerging from these publications.

“ENVIRONMENTAL” RISK FACTORS AND VASCULAR COMORBIDITIES

Cervical trauma is an important risk factor for CeAD [14, 15]. Rarely, CeAD can occur after a major penetrating or blunt trauma. Often, in about 40% of the cases, CeAD patients report a cervical trauma in the days or weeks preceding the dissection [16], although a causal relationship is often difficult to prove. These are mostly minor traumas, i.e., not leading to a

medical visit or hospitalization. Cervical manipulation therapy and cervical trauma during sports are significantly more common in CeAD patients than in age- and gender-matched patients with an ischemic stroke due to other etiologies [16].

Interestingly, anatomic factors, such as reduced distance between the internal carotid artery and styloid and hyoid bones, were recently shown to be associated with a higher risk of carotid dissections [17, 18]. It could be speculated that these anatomical factors may increase the susceptibility to CeAD after minor cervical trauma, but this remains to be proven.

Recent infection has been reported as a potential risk factor or trigger of CeAD [19-21], and acute CeAD is associated with high white blood cell counts compared to patients admitted for non-CeAD ischemic stroke (IS), i.e., IS due to other etiologies, or to healthy controls [22], possibly reflecting a pre-existing inflammatory state. On cervical high-resolution magnetic resonance imaging, patients with spontaneous CeAD more often have periarterial edema, often in conjunction with elevated C-reactive protein or erythrocyte sedimentation rate, than patients with traumatic CeAD [23].

A seasonal pattern in the incidence of CeAD has been described, with a higher incidence in autumn and winter. This may be attributable to an increased prevalence of infection, higher blood pressure levels, and winter sport practice [24].

Migraine is a risk factor for CeAD, approximately doubling the risk – the absolute risk remaining extremely small, given the low incidence of CeAD [25-27]. While migraine is also a risk factor for ischemic stroke of other etiologies [28], it is even more common in CeAD patients compared to age- and sex-matched patients with non-CeAD IS [29]. Moreover, CeAD is more commonly associated with migraine without aura (in contrast with non-CeAD IS, which is more strongly associated with migraine with aura). The mechanisms underlying this association are unclear, but may include shared genetic determinants (see below), common features of vascular dysfunction [30], such as endothelial dysfunction [31, 32], or other yet unknown factors.

Regarding vascular risk factors, their frequency was compared between 690 patients with CeAD and age-, gender-, and country-matched patients with non-CeAD IS (N = 556), and referents from the general population (N = 1,170) [33]. Compared to referents, CeAD patients were more frequently hypertensive (in line with an independently reported association with ultrasound markers of carotid stiffness [34]), and had a lower prevalence of hypercholesterolemia, obesity and overweight. All vascular risk factors were less common in CeAD patients compared to non-CeAD IS patients. These findings suggest that atherosclerosis is probably not a major predisposing condition to CeAD [35, 36]. It has also been speculated that lean persons may have less adipose tissue protecting the arteries from minor cervical traumas, and genetic pleiotropy may play a role (see below).

Finally, CeAD shows an intriguing correlation with other non-atherosclerotic vascular diseases [37], mainly fibromuscular dysplasia (FMD) and reversible cerebral vasoconstriction syndrome (RCVS).

FMD affects primarily the renal and extracranial carotid and vertebral arteries, although other arterial beds can be involved [38, 39]. The vast majority of patients are women (~90%) with a mean age at diagnosis of approximately 52 years, and a high prevalence of hypertension [40]. In the largest published FMD registry on over 400 patients, the frequency of CeAD in FMD was 12.1% when considering initial clinical manifestations, and 19.7% when considering CeAD events that had occurred prior to enrolment in the registry [40-42]. The frequency of FMD in CeAD registries varies widely, ranging between 5.6% in a large

recent multicenter series of 983 CeAD patients [43], and 16.5-21% in older single center series on 102 [44], or 62 CeAD patients [45], (the latter two being mostly investigated with digital subtraction angiography). The mechanisms underlying the association between CeAD and FMD are unclear, and may include common genetic risk factors (see below).

RCVS is a rare, underdiagnosed cause of severe headache with segmental constriction of cerebral arteries resolving within 3 months [46], facilitated by exposure to vasoactive drugs and the post-partum period. In a recent series of 173 RCVS cases and 285 CeAD patients, 20 patients (12% of RCVS and 7% of CeAD patients) had both disorders [47]. Underlying mechanisms of RCVS are unknown and reasons for the phenotypic overlap with CeAD remain elusive.

GENETIC RISK FACTORS

In rare instances, CeAD can occur as part of a monogenic condition (either as part of a known inherited connective tissue disorder or with a Mendelian inheritance pattern but unknown causal gene). In the vast majority of cases CeAD is believed to be a multifactorial, complex disorder.

Monogenic Forms of CeAD

Seldom, CeAD can occur as a complication of known, rare inherited connective tissue disorders [48], mostly vascular Ehlers-Danlos syndrome (caused by mutations in the *COL3A1* gene) [49], but also classic or hypermobile Ehlers-Danlos syndrome (caused by mutations in *COL5A1*, *COL5A1*), Marfan syndrome (*FBN1*), Osteogenesis Imperfecta (*COL1A1*, *COL1A2*), Loeys-Dietz syndrome (*TGFBR1*, *TGFBR2*) [50, 51]. These represent less than 1/1000 of CeAD patients hospitalized in departments of neurology [50]. However, a positive diagnosis of an underlying inherited connective tissue disorder, and precise molecular diagnosis thereof, can have important implications in terms of treatment, preventive measures and follow-up, as well as genetic counselling [52]. Patients with vascular Ehlers-Danlos syndrome for instance are at increased risk of vessel rupture secondary to endovascular investigations or procedures, at high bleeding risk under anticoagulants, and celiprolol is often prescribed to prevent vascular complications [53]. Hence it is important to screen patients for clinical features and a family history suggestive of an inherited connective tissue disease (of note, family history can be negative due to a high frequency of de novo mutations). It should also be noted that currently large published series of CeAD patients have not systematically screened patients for mutations in genes causing known, inherited connective tissue disorders. Pilot data suggests that such mutations may be more common than suspected based on clinical criteria [54-59], however this raises the question of the clinical significance of these mutations and the ethical relevance of such a systematic screening, which is currently not recommended. Next generation sequencing, which enables rapid sequencing of the whole genome or coding regions at increasingly affordable cost, is changing perceptions and leading to important ethical controversies around such questions, not only in the context of CeAD [60], and improvements in reliability of sequencing and

functional annotation of variants may potentially in the future lead to changes in paradigms in some instances.

Familial cases of CeAD are rare (1-2.5% in published series) and usually do not appear to occur in the context of a known inherited connective tissue disorder [61]. Linkage analyses have not identified any significant linkage peak to date, but their power was limited [62]. Next generation sequencing may provide novel insight into the genes underlying these familial forms in the near future. An increased risk of CeAD recurrence has been described in patients with a family history of CeAD [61].

Complex Forms of CeAD

In most CeAD cases, there is no evidence for an underlying monogenic disease and CeAD seems to occur as part of a multifactorial predisposition. Heritability estimates of apparently sporadic CeAD are not available in the literature. Numerous genetic association studies based on a candidate gene approach have tested the association of CeAD with single genetic variants, on relatively small samples [62-64]. Of these, 5 have reported significant associations with variants in 3 candidate genes: *ICAM-1* (rs5498) [65], *COL3A1* (3' UTR 2-bp deletion) [58], and *MTHFR* (*MTHFR*-C677T) [66-68]. The first two were not replicated and a meta-analysis supports a modest association between the *MTHFR*-677TT genotype and CeAD [62]. However, these studies were markedly underpowered. Moreover, candidate gene association studies are unable to identify novel genetic variants involved in unsuspected pathways [69]. A large, multicenter genome-wide association study (GWAS) of CeAD was recently completed by the CADISP consortium, using DNA samples from over 2,000 CeAD patients in total [12]. GWAS consist of genotyping large numbers of genetic variants distributed across the chromosomes, and has been applied to multiple complex diseases, including stroke [70-72], in the past few years, leading to important novel insight into disease pathophysiology. This first CeAD GWAS led to the identification of common intronic genetic polymorphisms in the *PHACTR1* gene associated with CeAD risk (the lower frequency allele [G] of the top variant, rs9349379, was associated with a lower risk of CeAD) [12]. This association was confirmed in an independent sample. Other highly suggestive associations were observed, with common variants in the *LRP1* gene and the *LNK1* gene, but these require confirmation in independent samples. While the *PHACTR1* variants were equally associated with carotid and vertebral artery dissections, the *LRP1* and *LNK1* variants were associated primarily with carotid artery dissection [12]. Intriguingly, independent GWAS have found the G allele of rs9349379 to be associated with a significantly lower risk of migraine (without aura) [73, 74] and fibromuscular dysplasia [75], and significantly increased risk of myocardial infarction and coronary calcifications [76, 77]. Opposite effects of the same genetic variant on different diseases have been described elsewhere [30], suggesting either that the same region harbors different causal variants or that the same causal variant has biological effects with opposite implications for each disease. This would be consistent with the aforementioned observation from epidemiological studies that CeAD is not associated with an atherosclerotic risk profile. *PHACTR1* being a major susceptibility locus for CeAD, migraine, fibromuscular dysplasia, and coronary artery disease, understanding the mechanisms by which this locus appears to influence key vascular functions could potentially have major applications for the treatment of these conditions [12]. Interestingly, recent analyses of tissue-specific gene

expression have shown that the G allele of rs9349379 is associated with significantly reduced *PHACTR1* expression levels in coronary arteries (data in cervical arteries are lacking). *PHACTR1* is located in a highly conserved genomic region, suggesting a crucial involvement in biological processes [39], but its function is poorly understood. Recent data suggest that *PHACTR1* regulates skeletal and cardiac alpha-actin gene expression, with its expression in the heart being modulated by direct mechanical stretching of cardiomyocytes – whether this applies to mechanical stretching of cervical arteries is unknown [78]. Other data suggest that disruption of phactr-1 pathway may trigger pro-inflammatory and pro-atherogenic factors in experimental models [79].

TREATMENT AND OUTCOME

At the acute phase of ischemic stroke caused by CeAD, intravenous thrombolysis is not contra-indicated based on current evidence [80-82]. Whether it is as efficient as for other etiologies of ischemic stroke is unclear [82].

Treatment at the acute phase of CeAD (with or without cerebral or retinal ischemia) currently consists mainly of antithrombotic therapy to prevent cerebral or retinal ischemia, either by anticoagulants or by antiplatelet agents. The choice between the two is based on empirical arguments, such as presence, size and distribution of brain infarcts [83, 84]. The main rationale for using anticoagulants, a primary choice in many centers, is the observation that the mechanism of ischemic stroke in CeAD is thromboembolic in the vast majority of cases (an assumption derived from the neuroimaging distribution of ischemic lesions) [85]. However, evidence for the superiority of anticoagulants versus antiplatelet agents is lacking. Several Cochrane systematic reviews and meta-analyses of observational studies do not suggest any difference between anticoagulants and antiplatelet agents on death and disability, or on risk of cerebral infarction [86-88]. A more recent meta-analysis using a Bayesian approach found weak evidence in favor of using antiplatelet agents vs. anticoagulants, but observed associations were no longer significant after keeping only high quality studies [89]. A phase 2 randomized trial testing the feasibility of a phase 3 randomized trial comparing anticoagulants to antiplatelet agents in acute CeAD was recently published [13]. Patients with CeAD with onset of symptoms within the past 7 days, and imaging evidence of definite or probable dissection, were randomized to receive anticoagulants (vitamin K antagonists with a target international normalized ratio between 2 and 3) or antiplatelet agents (chosen at the discretion of the practitioner). The sample size required for this feasibility phase was estimated at 250, based on rates of stroke recurrence reported in observational studies. After 3 months follow-up 3 out of 126 (2%) patients under antiplatelet agents versus 1 out of 124 (1%) patients under anticoagulants sustained a recurrent stroke, which did not differ significantly (OR = 0.33 [95%CI 0.01–4.23], $p = 0.63$). No death occurred, one patients suffered major bleeding (subarachnoid hemorrhage) in the anticoagulant group. Based on the number of events in both treatment groups the authors estimate that 10,000 participants would be required for a phase 3 trial, which, given the low incidence of CeAD, would require several years of recruitment by hundreds of stroke centers. Another important observation from this pragmatic feasibility trial is that central review of imaging failed to confirm dissection in 20% of patients. Although per-protocol analyses yielded similar results this is a

demonstration of the complexity of CeAD diagnosis despite well validated and published diagnostic criteria, highlighting the importance of centralized validation of inclusion criteria in trials but also non-interventional studies on CeAD. Further information may be obtained in the near future from the ongoing treat-CAD trial, run in Switzerland, that incorporates in the outcome the presence of novel “silent” cerebrovascular lesions (ischemia on diffusion weighted imaging, micro- or macrobleeds on T2* imaging) on follow-up MRI, in addition to recurrent clinical stroke (<http://clinicaltrials.gov: NCT02046460>). This may increase the number of events, but the clinical significance of these “silent” lesions will be a point of discussion.

In case of residual arterial abnormalities (stenosis, dissecting aneurysms or occlusion), long-term antiplatelet therapy is usually prescribed. If the dissected artery is completely recanalized no long-term antithrombotic treatment is required. The decision on whether to leave patients on long-term antiplatelet therapy is usually taken after 6-12 months. Indeed, epidemiological studies have shown that the dissected artery usually “heals” within the first 6 months and radiological changes are seldom observed beyond 1 year [5].

Importantly, the rate of recurrent or de novo cerebral ischemia after treatment initiation is low in CeAD patients (<3% in the largest observational studies and the CADISS trial) [9, 13, 87, 88, 90] with most events occurring in the first weeks after diagnosis. Similarly, CeAD recurrences are also rare and seem to be most frequent within the first months (2.1% at 3 months in a series of 900 CeAD patients [9]). While mortality rates after CeAD are very low and functional outcome is usually good (~75% of CeAD patients are independent at 3 months after stroke), the psycho-social impact of CeAD can be substantial, profound fatigue and important anxiety being the most common complaints.

CONCLUSION

To summarize, several large collaborative efforts have led to important new findings on the mechanisms and treatment of CeAD, including the first large reports on phenotypic overlap between CeAD and non-atherosclerotic vascular comorbidities, the first genome-wide association study of CeAD revealing a significant association with variants in PHACTR1 showing extensive pleiotropy with other vascular conditions, and finally publication of the first randomized feasibility trial on anticoagulants vs. antiplatelet agents in CeAD.

ABSTRACT

Stroke causes 9% of all deaths around the world and is the second most common cause of death, after ischemic heart disease. Since the majority of stroke cases are non fatal, its major burden is long-term disability among western people. After ischemic stroke, reactive oxygen species have been implicated to play a pivotal role in brain injury. Indeed, evidence reports a rapid increase in oxidative stress-related markers production immediately after acute ischemic stroke and that antioxidant defenses are rapidly overwhelmed, thus allowing further tissue damage. At high concentrations, these free radicals react and damage the cellular macromolecules leading to cell injury and necrosis. On the other hand, lower concentrations of reactive oxygen species behave as mediators in signaling involving mitochondria, DNA repair enzymes, and transcription factors that may lead to apoptosis after cerebral ischemia. When spontaneous reperfusion occurs, rapid restoration of blood flow increases the level of tissue oxygenation, accounting for a burst of reactive oxygen species that leads to the so-called reperfusion injury. Stroke is characterized by an ischemic core (infarct) surrounded by a “penumbra” (peri-infarct) region. In the penumbra area, where collateral blood flow can buffer the effects of vessel occlusion, cell death occurs less rapidly via oxidative stress-mediated mechanisms such as apoptosis and inflammation and thus, arises as an emerging target for therapeutic treatment. The currently applied measures to protect the brain against the severe damage caused by stroke have yielded insufficient improvement in the outcome of these patients. Thus, antioxidant strategies that lead to diminution of the oxidative injury are key to investigating new treatments to overcome the consequences of stroke. Evidence on acute

antioxidant system enhancement by means of use of NADPH oxidase inhibitor apocynin, xanthine oxidase inhibitor allopurinol, antioxidant vitamins C and E, the polyphenol resveratrol, as well as other antioxidant strategies are reviewed in the setting of stroke. Therefore, we introduce new strategies to be tested to reduce the cerebral damage related to both ischemia and reperfusion. This chapter reviews the mechanisms involved in ROS generation, the role of oxidative stress in the pathogenesis of ischemic stroke, the current strategies to treat ischemic stroke and new possible therapeutic strategies to treat this disease.

Keywords: Stroke, oxidative stress, antioxidant defense system

ABBREVIATIONS

BBB:	blood-brain barrier
CAT:	catalase
CNS:	central nervous system
COX:	cyclooxygenase

TBARS:	thiobarbituric acid reactant substances
TIA:	transient ischemic attack
VEGF:	vascular endothelial growth factor

INTRODUCTION

Stroke is the third most common cause of death in the population [1, 2]. Since life expectancy continues to grow in developed countries, the absolute number of individuals suffering from stroke will further increase in the near future [3]. The mortality rate in the acute phase of stroke is as high as 20% [1] and remains higher for several years after the acute event compared to general population [4].

The majority of strokes are non fatal, and the major burden is long-term disability. Therefore, it constitutes the most important single cause of severe disability among western people [5]. Because of the burgeoning elderly population in western societies, is estimated that by 2030 stroke-related disability in western societies will be ranked as the fourth most important cause of reduced disability-adjusted life-years (DALYs - the sum of life-years lost as a result of premature death and years lived with disability adjusted for severity) [6].

Stroke can be subdivided into 2 categories, ischemic and hemorrhagic. Ischemic strokes are more prevalent than hemorrhagic, making up approximately 87% of all cases, and being the target of most drug trials [7]. Classification based on the TOAST system [8] identifies the mechanism that leads to vessel occlusion (cardioembolic, artery to artery embolism, or in-situ small-vessel [lacunar] disease) and is important in the patient management because such information should influence both acute treatments and secondary prevention strategies [9]. A significant proportion of ischemic strokes is due to atherothrombosis which is related to several conditions associated with increased oxidative stress, such as hypertension, diabetes, dyslipidemia [10, 11].

RISK FACTORS

Aging is one of the most important risk factors for developing stroke. In fact, the majority of patients who experience stroke are older than 65 years [3]. Since a positive correlation between oxidative stress and aging has been reported [12], increased age could contribute to the occurrence of oxidative stress in the setting of stroke. There is a continuous association between both systolic and diastolic blood pressures and the risk of ischemic stroke [13]. Meta-analyses of randomized controlled trials confirm an approximate 30% to 40% stroke risk [14]. Diabetes is also a clear risk factor for stroke [15]. Hypercholesterolemia and hyperlipidemia are not as well established as risk factors for first or recurrent stroke in contrast to what is seen in cardiac disease [16]. In contrast, there is strong and convincing evidence that cigarette smoking is a major independent risk factor for ischemic stroke [17]. Obesity, defined as a body mass index of 30 kg/m², has been established as an independent risk factor for coronary heart disease and premature mortality [18]. The risk associated with smoking is present at all ages, in both sexes, and among different racial/ethnic groups [19]. In the other hand, most brain damage caused by stroke is a consequence of inflammation. Accordingly, plasma C-reactive protein levels have demonstrated to offer a valuable biomarker for tracking mortality from acute stroke, as well as risk of recurrent stroke [20].

Since a positive correlation between oxidative stress and all of this major risk factor has been reported, increased age, diabetes, obesity, hypertension and smoking could contribute to the worse evolution in the acute stroke event [12, 21-23]. Patients with these risk factors may have a lower antioxidant defenses functional reserve to cope with the stroke acute event.

Hypercholesterolemia and hyperlipidemia are not as well established as risk factors for first or recurrent stroke in contrast to what is seen in cardiac disease [16]. Monitoring lipid profile remains valuable; despite half of all strokes in the United States occur in people who do not have abnormal cholesterol or triglyceride levels [24]. In addition, multiple epidemiological studies have reported that high plasma homocysteine levels associate with increased risk for stroke [25]. Indeed, elevated plasma total homocysteine is associated with oxidative stress, hypercoagulability, increased cholesterol synthesis, abnormally reduced and dysfunctional

HDL-cholesterol, and endothelial dysfunction [26-30]. The effect of alcohol on stroke risk is controversial; however there is strong evidence that chronic alcoholism and heavy drinking are risk factors for all stroke subtypes [31].

PROTECTIVE FACTORS

Fruit and vegetable consumption has been associated with lower risk of stroke [32], which may be related to their antioxidant properties [21, 33]. Substantial evidence exists that physical activity exerts a beneficial effect on multiple cardiovascular disease risk factors, including those for stroke [34-36].

It is known that folate is the major metabolic recycler of homocysteine to methionine [37]. A recently published meta-analysis concluded that folate is effective in preventing stroke [38]. In the Heart Outcomes Prevention Evaluation 2 study, the combination of folic acid, vitamin B6, and vitamin B12 versus placebo for an average of five years demonstrated a significant stroke risk reduction [39].

PATHOPHYSIOLOGY

Oxidative Stress

Oxidative stress constitutes a unifying mechanism of injury of many types of disease processes, it occurs when there is a serious imbalance between the generation of ROS and the antioxidant defense system in the body so that the latter become overwhelmed [40].

ROS are a family of highly reactive species that are formed either enzymatically or non-enzymatically in mammalian cells. Superoxide ($O_2^{\cdot-}$) disproportionates quickly to oxygen and hydrogen peroxide (H_2O_2). In addition, various cellular oxidases, such as monoamine and amino acid oxidases, generate H_2O_2 . In the presence of redox-active iron, highly reactive and toxic hydroxyl radicals are generated from H_2O_2 and superoxide in the Fenton reaction and the Haber–Weiss cycle [41].

ROS are implied in both physiological and pathophysiological processes. For example, ROS play a beneficial role in the immune system by activating T lymphocytes and IL-2 production and mediating neutrophils and macrophages phagocytosis, participate in oxygen homeostasis, secondary messenger system and signal transduction [42- 44]. Particularly in CNS reactive oxygen species are mainly generated by microglia and astrocytes and modulate synaptic transmission and nonsynaptic communication between neurons and glia. In addition to these roles, ROS can induce synaptic longterm potentiation required for memory formation and evidence suggests that there is an age-dependent alteration in the role of $O_2^{\cdot-}$ in modulating synaptic plasticity, learning, and memory formation [45].

Superoxide is one of the most important ROS in CNS, but besides its above-mentioned role, it has also the potential to harm the ROS-producing cell, as well as neighboring cells. Superoxide is generated as a by-product of the respiratory chain or as a product of enzymes such as xanthine oxidase or NADPH oxidase. Although xanthine oxidase was identified early as a ROS source during neuronal reperfusion, other intracellular sources particularly NADPH

oxidase have been shown to produce ROS and contribute to oxidative stress during reperfusion [46]. NADPH oxidase type 4 (NOX4) is the most abundant vascular isoform; its expression is even higher in cerebral than in peripheral blood vessels [14] and, further, induced in stroke [15]. Therefore, it has been hypothesized that NOX4 is the most relevant source of ROS in stroke.

To avoid ROS-mediated cellular damage, such as lipid peroxidation, protein carbonilation, and DNA strand breaks, antioxidative mechanisms are present in cells that remove ROS or even prevent their generation. Low-molecular-weight antioxidants such as glutathione (GSH), vitamin C and vitamin E contribute to the antioxidant potential of cells. In addition, antioxidant enzymes such as superoxide dismutase (SOD), catalase (CAT), glutathione peroxidases (GSH-Px), and glutathione reductase (GR) are important for the cellular defense against ROS. H₂O₂ generated as a product of SODs is substrate of the heme-containing catalase that converts H₂O₂ to oxygen and water. In addition, GSH-Px uses GSH to reduce H₂O₂ to water.

Because of the short half-life of ROS, direct measurement within the brain is difficult in human subjects. The product formed by ROS attack to biomolecules constitutes a useful tool for oxidative stress assessment. Beyond the initial damage to membranes, reaction of these radicals with double bonds of fatty acids in lipids produces peroxides that give rise to α,β -unsaturated aldehydes including malondialdehyde (MDA), 4-hydroxynonenal and acrolein [47].

Figure 1. Role of oxidative stress in the pathophysiology of neuron injury after ischemic stroke, leading to infarct size and neurological morbidity and mortality.

Unlike other organs the brain is especially vulnerable to ROS due to low neuron antioxidant enzyme levels (catalase, glutathione peroxidase) and high concentrations of peroxidisable lipids, high oxygen consumption, and high levels of iron that act as pro-oxidants under pathological conditions [48]. In agreement with this view, free radical production has been reported as an important mechanism of brain injury after exposure to ischemia and reperfusion [49].

ISCHEMIA – REPERFUSION

Brain injury following stroke results from the effects of blood flow restriction caused by alterations such as thrombosis, embolism or systemic hypo-perfusion, basically resulting in cellular hypoxia and glucose deprivation. Ischemia initiates a complex cascade of metabolic events, several of which involve the generation of nitrogen and oxygen free radicals. These free radicals and related reactive species mediate most damage that occurs after transient brain ischemia in the penumbral region of infarcts [50] (figure 1). The pathological process involved after cerebral ischemic reperfusion injury are mainly oxidative stress, excitotoxicity, intracellular calcium overload, as well as inflammation and apoptosis [51].

The sequence of events begins at the mitochondrial level with a critical diminution in electron transport chain activity with the consequent ATP depletion [52]. Sequentially, once mitochondrial ATP synthesis has been inhibited by global ischemia, ATP consumption takes place within 2 minutes, causing neuronal plasma membrane depolarization, potassium leakage to the extracellular space and entry of sodium into cells [53]. This bioenergetic impairment also prevents the plasma membrane Ca^{2+} -ATPase from maintaining the normally low cytosolic calcium concentration.

Rapidly following cessation of blood flow, and the compromised energy metabolism quickly leads to large increases in neuronal activity and a resulting enhancement in glutamate release [54]. Neuronal release of glutamate following cerebral ischemia activates several types of pre- and post-synaptic glutamate receptors with the consequent rise in intracellular calcium concentration, determining an excitotoxic injury. High levels of intracellular Ca^{2+} , Na^{+} and ADP may lead to mitochondrial dysfunction, generation of reactive oxygen species, and the activation of proteases, phospholipases, and endonucleases, leading to cell death [55].

In addition, elevated extracellular glutamate concentrations can activate neuronal NOS via calcium influx [56]. As the level of superoxide ion is also elevated [57], the NO radical has dual effects: (1) to combine with superoxide anion to form highly pro-oxidant peroxynitrite and (2) to interfere with superoxide dismutase by reducing its antioxidant effect [58, 59].

Three distinct phases of ROS generation have been identified in cellular cultures, occurring with a specific temporal relationship to metabolic events taking place within the cells [60]. The first increase in ROS production during oxygen and glucose deprivation (OGD) coincide with the period of mitochondrial depolarization and that significant ROS generation ceased at the time that mitochondrial potential was completely collapsed. Inhibition of mitochondrial respiration by OGD inhibits cell respiration at complex IV, causes accumulation of reduced intermediates of the respiratory chain, and allows electron leakage to generate ROS [60]. The inhibition of the secondary increase of ROS production (after 25–35

min OGD or chemical ischemia) by xanthine oxidase inhibitors [60], strongly suggests a contribution of the enzyme in this response. It has been previously suggested that depletion of intracellular ATP leads to conversion of adenine nucleotides to hypoxanthine and xanthine, substrates for xanthine oxidase [61, 62].

It has been described that early reperfusion preserves penumbral brain tissue whereas late reperfusion increases ischemic damage [63]. Rapid restoration of blood flow increases the level of tissue oxygenation, leading to a third phase of ROS generation that causes the so-called reperfusion injury [64]. This phase can be blocked by NADPH oxidase inhibitors and was absent in cells from a NADPH oxidase – knockout (gp91^{phox} -/-) mice [60]. Also, activation of NADPH oxidase through Ca²⁺-dependent pathway was partly attributable to glutamate release and excitotoxicity. Furthermore, microdialysis of the striatum using sodium salicylate, which reacts with OH⁻ showed that this radical is formed mainly after reperfusion [65, 66]. Another study revealed that ROS generation during reperfusion was shown to be mainly in the endothelium and smooth muscle cells of small blood vessels [67], being likely to contribute to BBB disruption in vivo models.

We must highlight that in stroke patients another mechanisms contribute to the generation of free radicals. A major source of ROS in stroke patients are infiltrating neutrophils, microglia / macrophages and endothelial cells, accounting for another rise in ROS levels. Additionally, elimination of NOX4 remained beneficial in the absence of arterial recanalization in humans [68], suggesting that NADPH oxidase also participates before the reperfusion.

Histologically, stroke is characterized by an ischemic core (infarct) surrounded by a “penumbra” (peri-infarct) region. Within the core of the ischemic area, where blood flow is most severely restricted, excitotoxic and necrotic cell death occurs within minutes. In the penumbra area, where collateral blood flow can buffer the full effects of the stroke, cell death occurs less rapidly via oxidative stress-mediated mechanisms such as apoptosis and inflammation [69] and is an important target for therapeutic intervention. Cellular death mechanisms of penumbra are detailed below.

APOPTOSIS

The mode of cell death that prevails probably depends on the severity and precise nature of the ischemic injury. However, accumulating findings demonstrate that p53 is involved in neuronal death both in vitro hypoxic conditions [70, 71] and in vivo cerebral ischemic animal models [70, 72-74]. Moreover, levels of p53 and its products increase during early hours after ischemia onset and are especially high in the infarct border zone in focal cerebral ischemia models [75, 76], suggesting a key role in cellular death at the penumbra area.

Studies have emphasized the role of peroxynitrite in causing single-strand breaks in DNA, which activates DNA-dependent kinase and ataxia telangiectia protein, leading to activation, stabilization, and up-regulation of p53 [77-79]. The phosphorylation of p53 by stress-induced kinases reduces the affinity of p53 for MDM2 and enables a tighter association between p53 and its coactivators, such as the histone acetyl transferase (HAT) p300, increasing specific DNA binding at target genes.

INFLAMMATION

Interruption of blood flow to the brain leads to energy loss and necrotic cell death in the ischemic core. This initiates the immune response, characterized by a rapid activation of resident microglial cells and astrocytes, and by neutrophils and macrophages infiltration into the brain as demonstrated both in animal models and in stroke patients [80-84].

Four to six hours after ischemia, astrocytes become hypertrophic, followed by activation of microglial cells that evolve into an ameboid type with an enlarged cell body and shortened cellular processes [85-87]. In the other hand, within hours after the ischemic insult, increased levels of cytokines and chemokines enhance the expression of adhesion molecules, such as intercellular adhesion molecule 1 (ICAM-1) which reach a peak between 6 and 12 h after the onset of ischemia [88]. The increased expression of adhesion molecules can promote the adhesion and transendothelial migration of circulating monocytes and neutrophils.

Infiltrating neutrophils, microglia / macrophages and endothelial cells may release toxic amounts of NO mainly via the inducible NOS isoform, which is strongly induced following the ischemic injury both in animal models [89, 90] and in stroke patients [91] and also through activation of neuronal NOS [92]. NADPH oxidase expressed on the plasma membrane of the microglia can additionally contribute to the burst of ROS generation [93, 94].

During the first 2 hours after brain ischemia, NO produced by endothelial NOS exerts beneficial effects by promoting vasodilatation, decreasing platelet aggregation and leukocyte adhesion to the endothelium. Nevertheless, NO produced during later stages can rapidly interact with superoxide to form peroxynitrite, the key ROS in ischemic brain injury [95-97]. Furthermore, NO is responsible for cytotoxicity by inhibiting ATP-producing enzymes, by producing peroxynitrite and by stimulating other pro-inflammatory enzymes such as COX-2 [98].

As well as inflammatory cells are capable to produce ROS, ROS are capable to activate inflammatory cells via several mechanisms, determining a vicious circle. These mechanisms include ROS activation of NF- κ B, which is a highly redox-sensitive transcription factor mediating the activation of microglia, neutrophils and macrophages, and locally, ROS induction of the astrocyte expression of cytokines mediates activation of microglia [99].

Increasing evidence indicates that brain ischemia can also cause significant changes in the peripheral immune system [100-102]. Stroke causes neutrophilia, lymphocytopenia and an increase in the number of circulating monocytes [103]. However, although the increase in neutrophil and monocyte number is likely to contribute to ischemic damage, this change is also evident in patients that have experienced a transient ischemic attack [103], suggesting that infiltration to the brain would be the key determinant of whether these changes contribute to ischemic injury.

BLOOD BRAIN BARRIER DISRUPTION

It has been largely confirmed in cell culture models that ROS have a key role increasing permeability of the cerebral endothelium through the formation of actin stress fibers and migration of ZO-1 and occludin, accounting for the BBB disruption [104, 105].

There are two phases in BBB disruption. Early disruption of the BBB is likely to be primarily mediated by altered endothelial cell function. It has been reported that inhibition of the NADPH oxidase with apocynin was effective in maintaining early BBB function. Genetic deletion of gp91phox was also effective preventing early BBB dysfunction and offered protection from brain swelling after stroke, suggesting an important contribution of NADPH oxidase in early BBB disruption. Cellular origin of NADPH oxidase (i.e., leukocytes, microglia, neurons or endothelium) still remains unclear [106].

Late disruption is a consequence of inflammation, cell necrosis, production of tissue-degrading enzymes such as matrix metalloproteinases, and alterations in gene expression; therefore, late BBB disruption represents a very complex context [107-109]. ROS also participate in the late disruption, through matrix metalloproteases activation, degrading collagen and laminin in the basal lamina, which disrupts the integrity of the vascular wall and increases blood brain barrier (BBB) permeability. NO seems to be the most important molecule in terms of MMP interactions and it has been suggested to regulate MMPs via several routes. NO can directly activate MMP-9 by reacting with cystine residues in the propeptide domain of MMP-9 to form S-nitrosylated derivatives [110]. In addition, NO upregulates MMP-9 by increasing MMP-9 mRNA turnover [111].

The greatest significance of BBB disruption is that it results in tissue swelling and so increase regional tissue hydrostatic pressure. Thus it is possible that the primary disturbance of the barrier properties of the cerebral endothelium, leading to local tissue edema, will impose a constriction on the compliant vascular structures (i.e., the veins), resulting in reduced perfusion [112].

EDEMA FORMATION

Brain edema is a leading cause of death after stroke. Free radicals exert their deleterious actions leading to both cytotoxic and vasogenic edema, as it will be detailed below. Cytotoxic edema, which is defined as a swelling of cellular components in the brain, is the primary mechanism responsible for brain edema during the earliest phase of ischemic injury and results from cellular metabolic disturbances. All cellular elements (neurons, glia, and endothelial cells) take in fluid and swell but do not contribute to a net increase in brain volume because a corresponding reduction in the extracellular fluid space also occurs. Cytotoxic edema depends primarily on the duration and depth of ischemia and is an important indicator of ultimate infarct size and stroke severity.

The perturbation of ion transport perhaps plays the most important role in the pathophysiology of cellular swelling. It has been proposed an ion transporter modulation by ROS, including the peroxidation of membrane phospholipids, the oxidation of sulfadyl groups in ion transporters, and protein modification [113]. Indeed, iron-generated free radicals in vitro inhibit Na⁺, K⁺ -ATPase, Ca²⁺ -ATPase, calmodulin-associated Ca²⁺ -ATPase, and Na⁺ -Ca²⁺ exchanger activities [114].

Oxidative stress also supports the formation of cytotoxic edema through interaction with others mediators of cellular swelling. For example, lacticidosis is known to cause swelling of neurons and astrocytes triggering the release of iron from its binding site, which increases hydroxyl radical formation by increasing intracellular hydrogen peroxide levels and by

supplying protons during the chain reaction between superoxide and nitric oxide (NO) [115]. In addition, one study showed the potential contribution of ROS to AQP2 dysfunction in ischemia reperfusion-induced renal injury in a rat model [116].

In the other hand, vasogenic edema is caused by uncontrolled fluid leakage from the blood to the brain parenchyma through a weakened BBB and contributes to an actual net volume increase of the brain. Vasogenic edema is usually formed later than cytotoxic edema, after the cessation of cerebral blood flow; however, the disruption of the BBB can be demonstrated as early as 20 min after transient global forebrain ischemia.

As discussed above, free radicals such as superoxide and NO exert direct effects on mediators of BBB disruption such as leukocytes, inflammatory response, MMP and microvascular integrity. ROS also contributes to VEGF expression, leading to vasogenic edema. Moreover, a vascular NADPH oxidase, a main source of vascular superoxide, is involved in VEGF expression [117].

OXIDATIVE STRESS BIOMARKERS

Finally, it must be emphasized that stroke is an important factor in the overall antioxidant capacity and ROS production [118, 119].

The size and type of the stroke is an important factor in the overall antioxidant capacity and oxidative stress. Several studies described increased levels of lipid peroxidation markers in stroke patients, such as MDA assessed by TBARS [120-122] and by HPLC [123, 124], and lipid peroxides [120, 125], in plasma and erythrocytes.

Plasma levels of various nonenzymatic endogenous antioxidant systems, such as vitamin C [118, 122, 123], vitamin E [121], vitamin A, and uric acid [118], were also reported to be lower in patients with ischemic stroke than in a healthy control population.

These data suggest that either the aforementioned antioxidants are consumed or oxidized during the cerebral ischemia reperfusion event or that their levels are lower already before the stroke.

Data regarding the activity of some antioxidant enzymes are rather contradictory. Some studies observed an augmentation of SOD concentration in plasma [126] or cerebrospinal fluid (CSF) [126, 127], while others measured a decrease in plasma [118, 128] or erythrocytes [124] or even no modifications in erythrocytes [120]. Reduced GSH-Px activity was demonstrated in erythrocytes [124], whereas this activity appeared increased in total blood [120].

These oxidative stress markers also seem to be useful as prognostic predictors of stroke outcome. Several studies has shown that brain damage and post-ischemic neurological deficit are correlated with concentrations of SOD 1 and 3 in CSF [127], lipid peroxides in plasma [125], MDA by HPLC and MDA by TBARS in erythrocytes [120, 124], and also the extracellular production of free radicals by peripheral phagocytes [120]. A significant positive association between plasma lipid hydroperoxide concentration and the National Institute of Health Stroke Scale has been reported and a significant negative correlation with the Glasgow Coma Scale [125].

On the contrary, histological and neurological parameters have been demonstrated to be negatively correlated with plasma levels of vitamins C, vitamin E [129], and uric acid [130],

plasma total antioxidant activity [129], SOD activity in plasma [128] or in erythrocytes [124], and GSH-Px activity in erythrocytes [124].

NON-ANTIOXIDANT ACUTE INTERVENTIONS FOR STROKE MANAGEMENT

Stroke Care Units (SCU)

One of the most substantial advances in stroke has been the routine management of patients in stroke care units (SCU), which is effective and appropriate for all stroke subtypes, and provides a focus for professionals in stroke care. Management of patients within an SCU reduces mortality by about 20% and improves functional outcome by about the same amount [131]. A physical space identified as an SCU is associated with better outcomes than seen with a dedicated stroke team, visiting patients on general medical wards [132]. The important characteristics of stroke unit care within the randomized trials were the provision of coordinated multidisciplinary rehabilitation, staff specialisation in stroke or rehabilitation, and improved education and training [133]. These nonspecific actions of neuroprotection are also in the context of improving the cellular function, oxygenation and thus decreasing the oxidative stress. It has been reported that SCU was associated with better long-term survival, but younger patients, patients with intracerebral haemorrhage and patients who were unconscious had the best relative effect and may be given the highest priority to this form of care [134].

Revascularization Techniques in the Acute care

Intravenous Thrombolysis

Existing therapeutic interventions to reduce infarct size are limited to thrombolysis [135]. Thrombolysis is the only intervention currently approved by the U.S. Food and Drug Administration (FDA); it does not work effectively for many patients, being effective if applied within 4.5 hours of symptom onset [136]. In fact, in the US, only roughly 2% of stroke patients benefit from access to early thrombolysis [137]. Due to the strict time constraints for intervention, inadequate readiness at some hospitals, substantial risk of intracerebral hemorrhage, restrictive patient selection criteria, and other factors such as transport to the treatment facility, only one to three percent of stroke patients receive rtPA treatment. The major risk from rtPA intervention is hemorrhage, being its incidence around six percent [138].

Intra-arterial Thrombolysis

PROACT II is the first randomized multicenter trial to demonstrate the clinical efficacy of intra-arterial thrombolysis in patients with acute stroke of less than 6 hours' duration caused by MCA (middle cerebral artery) occlusion [139]. Direct intra-arterial delivery of fibrinolytic agents is reportedly more effective to recanalize major symptomatic cerebral arterial occlusions than intravenous delivery [140]. Combination therapy of intravenous and

intraarterial infusion of recombinant tissue plasminogen activator (rtPA) has benefits in patients with acute major cerebral artery ischemia [141].

Mechanical Thrombectomy

Endovascular mechanical thrombectomy may be used during acute ischemic stroke due to large vessel intracranial occlusion. Endovascular mechanical thrombectomy can restore vascular patency of carotid terminus or basilar artery occlusions between 41% and 54% of the time, providing an alternative or synergistic method to restore blood flow [142].

Anticoagulant and Antiplatelet Drugs

The current stroke guidelines accepts interventions to diminish platelet aggregation can reduce the risk for recurrent stroke in patients with an acute episode, recommending aspirin as the single antiplatelet drug adequately validated for this purpose. Aspirin is classified as adjunctive therapy to rtPA, and should not be started earlier than 24 hours after the onset of stroke. In patients who do not receive thrombolysis, aspirin is started from the diagnosis [143]. Clopidogrel has been the most common therapy received in the long-term care by these patients and still requires further research [144]. Treatment with GPIIb/IIIa antagonists is associated with increased mortality [145]. Warfarin remains one of the most biologically effective secondary prevention strategies for patients with atrial fibrillation and reduces the relative risk of recurrent stroke in patients with TIA or minor stroke by about 70% [9]. In the secondary prevention, the use of Aspirin plus extended-release dipyridamole is much better than the use of Aspirin alone [146].

Non-pharmacologic Neuroprotection

Airway, Ventilatory Support and Oxygen

Airway support and ventilatory assistance are recommended for the treatment of patients with acute stroke who have decreased consciousness or who have bulbar dysfunction causing compromise of the airway [147]. Hypoxic patients with stroke should receive supplemental oxygen [148].

Temperature Management

Increased body temperature in the setting of acute ischemic stroke is associated with poor neurological outcome (increased risk of morbidity and mortality), possibly secondary to increased free radical production, increased metabolic demands, and enhanced release of neurotransmitters [149]. It is generally agreed that sources of fever should be treated and antipyretic medications should be administered to lower temperature in febrile patients with stroke [150].

Blood Pressure

The management of arterial hypertension remains controversial. Both elevated and low blood pressures are associated with poor outcome after stroke [151]. It is generally agreed

that patients with markedly elevated blood pressure may have their blood pressure lowered. In the other hand, the cause of arterial hypotension in the setting of acute stroke should be sought. Hypovolemia should be corrected with normal saline, and cardiac arrhythmias that might be reducing cardiac output should be corrected [143].

Glucose Management

It is generally agreed that hypoglycemia should be treated in patients with acute ischemic stroke. The goal is to achieve normoglycemia. Marked elevation of blood glucose levels should be avoided [152].

Pharmacological Neuroprotection

Albumin

In several animal models of ischemic stroke, albumin infusion reduced infarct size and swelling, improved local perfusion to zones of critical blood flow reduction, and improved neurological and behavioral functions [153]. In a clinical trial conducted by Shin et al. [154], patients with moderate to severe ischemic stroke in the area of the middle cerebral artery were randomized within 12 hours after symptom onset. Although infarct volume continued to increase in control and albumin groups, when measured at 72-96 hours after onset, the volume increase was significantly less in the albumin-treated patient group as a whole (26.0% increase versus 67.2% increase for albumin and control groups, respectively). This protein has a prolonged circulating half-life (about 20 days), and its high molecular weight keeps it in the blood vessel lumen, drawing in water and thereby expanding intravascular volume [154]. Albumin is also a potent antioxidant, a large molecule carrying a high density of cysteine groups [155]. Albumin clearly has strong benefit in acute ischemic stroke, without troublesome adverse effects. Besides having the advantage that it can be applied anytime within 24 hours of stroke onset, as shown in the Shin trial [156], albumin is cost-effective compared to other in-hospital interventions.

Magnesium Sulfate

Ionized magnesium has demonstrated effective neuroprotection in animal models of cerebral ischemia, excitotoxic injury, head trauma, and spinal cord damage [157]. The international Intravenous Magnesium Efficacy in Stroke (IMAGES) trial suggests that magnesium has neuroprotective potential for acute ischemic stroke [158]. Although it found no statistically significant overall benefit, it did show a trend toward protection for patients with noncortical stroke [158]. FAST-MAG is a large, controlled trial with the statistical power to detect modest treatment effects of intravenous magnesium sulfate for very early stroke; this trial is in progress. This unique trial hopes to demonstrate pre-hospital initiation whether magnesium infusion therapy, mostly via paramedics, can be effective in halting or slowing the ischemic cascade in most patients within those first crucial two hours.

Hypothermia

Hypothermia slows cerebral metabolism and protects neurons subjected to acute ischemia. This is a potent intervention that improves neurological outcomes after cardiac

arrest and has been used to treat patients with severe brain edema [159]. Because the optimal body temperature for stroke management is not yet clear, caution must be taken since excessive cooling could precipitate adverse effects such as hypotension, cardiac arrhythmias, or infections [142]. Furthermore, after applying hypothermia and intravenous magnesium in animal experiments, Meloni et al. [160] suggest concomitant use of both interventions in patients should improve the overall neuroprotective outcome.

Other Pharmacological Strategies

After many promising animal studies, a human pilot study – the Goettingen EPO-Stroke Study – examined erythropoietin (EPO) for stroke [161]. EPO given intravenously readily crossed the blood-brain barrier. It was proven safe and demonstrated significantly better outcomes compared to placebo. Thus, EPO patients experienced significantly less neurological deficit, better restitution of brain function, and significantly smaller lesion size than controls.

Lubeluzole was tested in several clinical trials [162] Although a pilot study suggested that the agent was safe and might reduce the death rate, subsequent larger clinical trials found no effects in reducing deaths or improving outcomes after stroke [163].

Citicoline is an agent that apparently stabilizes membranes, has been tested in several clinical studies [164]. The trials did not demonstrate efficacy from treatment. A subsequent meta-analysis reported that patients with moderate to severe stroke might be helped if the medication was started within 24 hours of onset of symptoms [165]. This finding should not be considered definitive but rather a rationale for further testing of the medication in this subgroup of patients.

Piracetam also has been tested in several clinical trials, with mixed results [166, 167]. Although the agent may be effective in some patients with ischemic stroke, the data are not sufficiently clear to draw a conclusion about the utility of this medication.

There was no indication that careful blood-pressure lowering treatment with the angiotensin-receptor blocker candesartan is beneficial in patients with acute stroke and raised blood pressure. If anything, the evidence suggested a harmful effect [168].

THE ROLE OF ACUTE ANTIOXIDANT DEFENSE SYSTEM ENHANCEMENT IN ISCHEMIC STROKE TREATMENT

There is a substantial need for further research on agents able to significantly reduce the cerebral damage related to both ischemia and reperfusion. These agents might be particularly important not only in those patients who cannot receive thrombolysis but also in those who, undergoing this type of treatment, are at risk of the so-called reperfusion injury. Antioxidants have been evaluated as neuroprotective agents in stroke [169] since there is evidence supporting the occurrence of oxidative stress during brain ischemia. The therapeutic use of most studied antioxidants against stroke-induced brain damage is discussed below. A summary of the proposed antioxidant strategies can be found on figure 2.

Figure 2. Therapeutic opportunities along the time course of oxidative stress development in the setting of ischemic stroke.

Inhibition of ROS-producing Enzymes

NADPH Oxidase Inhibition

Superoxide producing NADPH oxidase has been shown to contribute to oxidative stress-mediated brain injury during both ischemia and reperfusion. Apocynin (4-hydroxy-3-methoxyacetophenone, trivial names: apocynin, acetovanillone) has been used as an efficient inhibitor of the complex NADPH oxidase in many experimental models [170, 171]. The mechanism of inhibition has not yet been fully elucidated. In leukocytes, apocynin is a prodrug that is activated by myeloperoxidase, a process that results in the formation of apocynin dimers [172], which have been shown to be more efficient than apocynin itself [173, 174]. Endothelial cells and smooth muscle cells failed to form these dimers and, therefore, are not able to activate apocynin [172]. It has been demonstrated that treatment with apocynin can attenuate brain injury after experimental ischemic stroke in the hippocampus after global cerebral ischemia [175-177].

In a recent study, treatment of apocynin 5 minutes before reperfusion attenuated cerebral injury in a 24-hour ischemia model in rats [178]. Administration of apocynin showed marked reduction in infarct size compared with that of control rats. Medial carotid artery occlusion-induced cerebral ischemia was also associated with an increase in, nitrotyrosine formation, as well as IL-1 β expression, I κ B degradation and ICAM expression in ischemic regions. These expressions were markedly inhibited by the treatment of apocynin. It was also demonstrated that apocynin reduces levels of apoptosis (TUNEL, Bax and Bcl-2 expression) resulting in a reduction in the infarct volume in ischemia-reperfusion brain injury [178].

It has been demonstrated that pharmacological inhibition of NADPH oxidases using the specific NADPH oxidase inhibitor Vasopharm (VAS2870) [179-182] protects mice from brain ischemia within a clinically meaningful 2-h time window [68]. This protection resulted in decreased infarct volume, reduced oxidative stress, neuronal apoptosis, and blood-brain-barrier leakage and increased neurological score, motor function and survival.

In contrast, commonly used apocynin may not be a NADPH oxidase inhibitor in vascular cells but rather acts as a nonspecific antioxidant [172], also inhibiting Rho kinase inhibitor [183], an activity that increases its nonspecific actions. If apocynin inhibits NADPH oxidases at all, it supposedly blocks the migration of the cellular NADPH oxidase complex subunit p47phox to the membrane, thus interfering with assembly of the functional NADPH oxidase complex [184]. Therefore, it is unlikely to inhibit the NOX4-containing NADPH oxidase, which acts independently of any cytosolic subunits [185]. Indeed, application of apocynin had no effect on the formation of ROS or of functional outcome after experimental stroke in vivo in a NOX4 *knock out* model [68].

Allopurinol

Ischemia-induced depletion of intracellular ATP leads to accumulation of hypoxanthine and xanthine, substrates for ROS-producing xanthine oxidase which is one of the main sources of ROS in the setting of ischemia-reperfusion [186]. Allopurinol is an inhibitor of the xanthine oxidase enzyme; furthermore, with its metabolite oxypurinol have been suggested to scavenge hydroxyl radical [187]. In addition, evidence suggests that hypoxic and reperfusion injury to the cerebral vasculature, especially to the endothelial cells, is dependent on xanthine oxidase [188, 189].

Allopurinol is an inhibitor of the xanthine oxidase enzyme, which is thought to be the main source of ROS in the setting of ischemia-reperfusion [186]. Among the molecules preventing the formation of free radicals, xanthine oxidase inhibitors, such as allopurinol or its metabolite oxypurinol, reduced cerebral infarct size and edema in permanent ischemia [190-193].

Allopurinol was found to be protective against mortality and neurological impairment in a stroke model in spontaneously hypertensive rats [194]. In a permanent middle cerebral artery occlusion model in Sprague-Dawley rats, allopurinol pretreatment reduced infarct size by approximately 35% [195]. Similar to allopurinol in a rat model of transient middle cerebral artery occlusion, its metabolite oxypurinol reduced the ischemic cerebral damage and attenuated the neurological deficits [192, 193, 196]. Allopurinol was also effective in a rabbit model of focal cerebral ischemia [197] and in hypoxic-ischemic injury models in rat pups, as well as in newborn lambs, even if its administration was delayed to the beginning of the reperfusion period [198-200]. Allopurinol, at relatively high doses, was also effective in transient middle cerebral occlusion models [190]. In a relatively mild model of stroke (20 min of ischemia and 10-90 min of reperfusion), oxypurinol produced improvements in cellular ATP levels [201]. It must also be mentioned that in some studies oxypurinol was without significant protective effects [202, 203], and the reasons for these differences between the outcome of these various studies are unclear.

Nevertheless, in vitro studies clearly demonstrate that, at least in rodents, hypoxia and reoxygenation increase the activity of xanthine oxidase and xanthine deshydrogenase, possibly due to a direct action of excitatory amino acids such as kainate [204-206]. In addition, there is some evidence that the hypoxic and reoxygenation injury to the cerebral

vasculature, especially to the endothelial cells, is dependent on xanthine oxidase [188, 189]. So far, the human therapeutic experience with allopurinol is limited to one study conducted in 22 severely asphyxiated infants [207]. In this study, allopurinol tended to improve survival, and exerted beneficial effects on free radical formation, cerebral blood flow volume, and electrical brain activity. Larger follow-up studies are required to expand on these pilot findings [208]. Interestingly, a recent study has shown increased xanthine oxidase activity being partially responsible for the generation of oxygen free radicals in a rat model of traumatic brain injury, suggesting that inhibition of xanthine oxidase may be of potential therapeutic benefit in neurotrauma [209].

Antioxidant Supplementation to Scavenge ROS

Vitamin C

Vitamin C is a potent water-soluble antioxidant in humans. Its role as a free radical scavenger and its redox relationship with other antioxidants has been the focus of continuous interest [210].

It is important to remark that differently to typical drugs, the half-life of vitamin C depends on its plasma levels. Accordingly, when plasma levels are above 70 $\mu\text{mol/L}$, ascorbate has a half-life of about 30 minutes [211]. However, in periods of deficient intake, when the renal transporters actively reabsorb the vitamin preventing acute scurvy, the plasma half-life of ascorbate is widely reported to be between 8 to 40 days [212]. Regarding absolute bioavailability, from 70 to 90 percent of usual dietary intakes of ascorbic acid (30 to 180 mg/day) are absorbed [213], although absorption decreases to about 50 percent and less with single doses above 1 gram [212, 214]. Therefore, large doses of vitamin C should be given intravenously in order to achieve high plasma concentrations of this compound.

Ascorbate uptake and content in neurons will be limited by the number of SVCT2 expressed proteins, and affinity for ascorbate becomes relevant only when ascorbate deficiency is present [215]. Indeed, vitamin C is accumulated in some cells in part by the sodium-dependent transporter with saturable kinetics [211]. Ascorbic acid is concentrated mainly in the brain and adrenal gland, among others [216, 217]. Even though glia may not normally express the SVCT2, oxidative stress due to ischemia–reperfusion injury has been shown to increase SVCT2 mRNA expression in both neurons and glia [218].

Ascorbate directly scavenges oxygen- or nitrogen-based radical species generated during normal cellular metabolism [215]. The major radical byproduct of mitochondrial oxygen metabolism is superoxide [219]. Ascorbate concentrations of 100 μM and higher are required to appreciably scavenge superoxide [220]. Vitamin C behaves as an enzyme modulator, exerting up-regulation on endothelial NO synthase (eNOS) and downregulation of NADPH oxidase [221].

Thus, vitamin C counteracts and prevents the oxidation of lipids, proteins and DNA, subsequently protecting their structure and biological function. Ascorbate has been shown to spare/recycle α -tocopherol in lipid bilayers [222] and in erythrocytes [223], therefore, enhancing vitamin E antioxidant properties. Given the lipid-rich environment of the brain, the sparing or recycling of α -tocopherol may be a very important role for ascorbate. Accordingly, when ascorbate is added to cultured cells, brain slices, and brain microsomes it prevents lipid

peroxidation induced by various oxidizing agents [224, 225], especially in combination with α -tocopherol [226, 227].

Perhaps the most dramatic acute oxidative stress in the CNS is the ischemia–reperfusion injury that occurs with ischemic stroke. Ischemia initially depletes intracellular ascorbate [228] and GSH [229] in the brain. If reperfusion with oxygen-rich blood occurs, the ROS generated by abnormal mitochondrial metabolism will extend tissue damage to areas with decreased oxidant defenses [230].

In a Chinese study, plasma vitamin C levels were inversely correlated with stroke mortality [231]. Several studies investigated the plasma vitamin C levels in patients suffering from acute stroke, finding lower levels compared to healthy controls [121, 123, 129, 232]. These studies also demonstrated that vitamin C plasma levels decrease in the first hours following cerebral ischemia [123] and tend to recover in the following days [188]. However, there are also studies that did not show any difference of vitamin C concentrations between stroke and control patients [233].

There are only three studies concerning the effect of vitamin C on the outcomes of acute ischemic stroke. In 59 stroke patients admitted to the hospital within 24 hours, Polidori and colleagues demonstrated that those randomized to aspirin 300 mg plus vitamin C 200 mg/day had slightly lower levels of lipid peroxidation markers (8,12-iPF_{2a}) compared to those taking aspirin alone [234]. In this pilot study no difference in clinical outcomes occurred between the two groups.

Ulegaddi and colleagues found that antioxidant supplementation (500 mg of vitamin C plus 800 IU of α -tocopherol) administered within 12 hours from the onset of symptoms and continued up to 14 days in acute ischemic stroke patients is able to enhance antioxidant capacity and to mitigate oxidative damage [235].

A recent study showed that vitamin C 500 mg/day IV alone resulted in increased plasma total antioxidant capacity, but it did not substantially improve the clinical and functional status of patients after 3 months [236].

Parenteral ascorbate injections decreased infarct size in both primate and rodent models of middle cerebral artery ischemia–reperfusion. When monkeys were given 1 gram/day of ascorbate parenterally for 6 days before middle cerebral artery occlusion, brain infarct size was decreased by 50% in the ascorbate-treated group compared to the control group not treated with ascorbate [237]. Ascorbate was measured in the basal ganglia of these animals and was found to increase 50% above levels in the treated compared to the untreated monkeys [237]. Thus, relatively modest increases in brain ascorbate content due to several days of parenteral administration were associated with neuroprotection against ischemia–reperfusion injury. In another primate study, high-dose ascorbate (500 mg/kg up to 2 g) was administered into the middle cerebral artery just before occlusion, which was maintained for 4 hours. At 24 hours after reperfusion, the mean infarct size in ascorbate-treated monkeys was only one third of that in untreated controls.

Pre or post-treatment with the blood–brainbarrier-impermeant vitamin C seems unable to reduce cerebral infarct volume at a dose of 500 mg/kg IV 3 hours post-middle cerebral artery occlusion [238], whereas the BBB-permeant dehydroascorbate (DHA), reduces the lesion volume by 50–90% in rats [238]. Consequently, based on the delayed rupture of BBB after cerebral ischemia, it seems important to develop molecules crossing the BBB. Recently, the selective hydroxyl radical scavenger EPC-K1, a phosphate diester of vitamins C and E able to penetrate the BBB, has been reported to reduce infarct size and lipid peroxidation, evaluated

by TBARS levels, after transient ischemia [239, 240]. Moreover, the study of Takamatsu et al. [240] indicates that the most critical period of hydroxyl radical formation for ischemic brain damage may occur a few hours after ischemia.

In a subsequent study in mice with middle cerebral artery occlusion, high-dose DHA given by intraluminal infusion injection just before, 15 minutes after, or 3 hours after occlusion markedly decreased infarct volume, mortality, and neurological deficits in mice [238]. Protection by DHA infusion was observed in both ischemia alone and ischemia–reperfusion models. A subsequent study by the same group replicated the initial results in mice and further showed that post-ischemic DHA infusion prevented the 50% decrease in brain ascorbate and also largely prevented the increase in lipid peroxidation due to ischemia–reperfusion injury [241].

Vitamin E

Vitamin E, a fat-soluble vitamin known to be one of the most potent antioxidant, acts by breaking the propagation of the free radical chain reaction in the lipids of biological membranes and reduces infarct volume by 45–55% in permanent and transient models of cerebral ischemia. Vitamin E is probably the most studied antioxidant for its potential use in the prevention and treatment of ischemic cerebrovascular disease in randomized controlled trials. The protective effects of vitamin E are more consistently found in secondary prevention trials.

A lower incidence of stroke has been demonstrated in a small number of patients with previous stroke taking aspirin (325 mg/day) and vitamin E (400 IU/day) versus those on aspirin alone [242]. The Secondary Prevention with Antioxidants of Cardiovascular disease in End-stage renal disease (SPACE study) was performed in 196 hemodialysed patients with pre-existing cardiovascular disease. In this study, participants who received 800 IU/day of natural α -tocopherol experienced a decrease of the primary combined end-points (i.e., myocardial infarction, ischemic stroke, peripheral vascular disease and unstable angina) [243].

In the largest study ever performed on the subject, the Nurses' Health Study, about 87,000 women were followed-up for an average of 8 years: participants taking vitamin E supplements had a reduced risk of ischemic stroke while they had a lower risk of coronary events [244].

Diet supplementation with vitamins, such as vitamin E, also induces a neuroprotection after ischemia [245–247]. An appreciable beneficial effect was also achieved with prophylactic oral administration of the vitamin E/lipoic acid mixture from 30 days before the ischemic event [247], suggesting that such a combination may be valuable in reducing brain damage in patients with a high risk of stroke [118]. Lipoic acid exerts its antioxidant effect by scavenging hydroxyl radicals, singlet oxygen, and nitric oxide. In addition, it chelates transient metals, recycles others antioxidants, such as vitamin E and C, and raises also intracellular levels of glutathione.

γ -tocopherol, an isoform of vitamin E, has been shown to inhibit lipid peroxidation damage and to trap reactive nitrogen species more efficiently than α -tocopherol [248]. Moreover, the administration of γ -tocopherol by bolus intravenous injection in rats immediately before and 3 hours after the MCA occlusion reduced the infarct volume more than α -tocopherol [249].

Recent studies in humans have reported an association between the plasma concentration of ascorbic acid and α -tocopherol and early clinical outcome after acute ischemic stroke [118, 129].

Supplementation with antioxidant vitamins within 12 h postinfarct after acute stroke increased plasma antioxidant capacity and reduced lipid peroxidation products. However, differences in total antioxidant capacity and MDA were only significant during the first week. This occurred in association with a predicted increase in the plasma concentration of ascorbic acid and α -tocopherol. Plasma C reactive protein was also lower in those stroke patients who received antioxidant supplements compared with controls at 7 and 14 days [250].

According to studies in stroke patients, the supply of vitamin E (727 mg/day) together with vitamin C (500 mg/day) reduced peroxidation of lipids and exerted anti-inflammatory effects [250, 251]. Hence, to define the usefulness of vitamin C for stroke therapy, its pharmacokinetics should be assessed to find the optimal daily dose, frequency and route of administration. In addition, vitamin C may work better in combination with other pro- or antioxidative agents [236].

A recent uncontrolled study of 22 ischaemic stroke patients reported an association between the plasma concentration of ascorbic acid and α -tocopherol and the degree of neurological impairment after ischaemic stroke [129]. The same study demonstrated an association between plasma total antioxidant activity and the volume of ischaemic cerebral infarction and the degree of subsequent neurological impairment.

Resveratrol

Hydroxystilbenes, naturally occurring polyphenolic compounds, are also well known for their free radical scavenging properties. Resveratrol (3,5,4V-trihydroxystilbene), one of the major components of red wine, is a representative of this group and was found to prevent lipid peroxidation [252]. Besides antioxidant activity, resveratrol may protect against brain damage via several mechanisms. Resveratrol activates the PPAR- α and PPAR- γ receptors which are recognized to have anti-inflammatory actions. This effect has been partially confirmed in PPAR- α knockout mice where resveratrol does not reduce the infarct volume after MCA occlusion [253].

To date, two studies have demonstrated that this compound could reduce the size of cerebral infarction, and this neuroprotective effect has been associated with an inhibition of rise in MDA and GSH levels induced after ischemia [254]. Recently, the naturally analogue oxyresveratrol (trans-2,3V,4,5V-tetrahydroxystilbene), which scavenges hydrogen peroxide and nitric oxide, was also shown as a potent neuroprotectant in a model of transient cerebral ischemia [255].

In mice, a single dose of resveratrol given orally 1 hour before permanent MCA ligation does not protect against ischemic damage, while given daily for 3 days before ischemia it significantly reduces the infarct size [253]. Other studies confirmed that resveratrol might reduce cerebral ischemic damage in different animal stroke models [253, 256]. Gerbils injected with resveratrol intraperitoneally experienced decreased neuronal death in the hippocampus and had lower glial cell activation either during or shortly after common carotid artery ligation and 24h later [257].

In mice, resveratrol reduces the elevated levels of metalloproteinase-9 (MMP-9), which is induced by cerebral ischemia-reperfusion [258]. By using in vitro neuronal cultures, resveratrol has been shown to induce a neuroprotective enzyme, i.e., heme oxygenase1, that is

believed to be protective by counteracting the intracellular increase of heme, a pro-oxidant agent [258, 259]. Finally, recent studies show that resveratrol may be beneficial miming ischemic preconditioning via the Silent Information Regulator T1 (SIRT1) pathway. SIRT is a NAD⁺-dependent histone deacetylase, which has been shown to inhibit stress-induced apoptosis and to increase cellular tolerance to stress [260]. During ischemic/reperfusion damage this sirtuin molecular pathway induced by resveratrol increases neuronal cell survival in an unfavourable environment [261].

N-acetylcysteine (NAC)

NAC has been reported to effectively scavenge ROS, such as hydroxyl radicals, hydrogen peroxide, and peroxy radicals, and also to increase the rate of endogenous glutathione synthesis [262]. Glutathione, which is a central component in the antioxidant defense of cells, acts either directly or indirectly as a substrate for various glutathione peroxidases to detoxify free radicals [263]. Thus, it is expected that NAC is able to reduce the volume of postischemic lesion. For instance, Carroll et al. [264] showed a 49 or 29% reduction of the lesion size, when NAC is administered prior or after the reperfusion, suggesting that the oxidative stress occurring during reperfusion exerts a more important deleterious effect than during ischemia.

A recent study demonstrated that NAC administration protects the brain from free radical injury with a therapeutic window effective up to 6 h after reperfusion, and this neuroprotection is associated with increased glutathione levels [265]. Moreover, repeated administration of NAC is more neuroprotective than a single dose, perhaps because of the short half-life of this antioxidant [262]. The administration of its monoethyl ester derivative was demonstrated to be neuroprotective for the first time after the intracerebroventricular infusion for the entire ischemia/reperfusion period [228].

Other Antioxidant Strategies

B-group vitamin supplementation immediately postinfarct may have antioxidant and anti-inflammatory effects in stroke disease independent of their homocysteine-lowering effect [251]. The important findings of this study were that supplementary antioxidants with or without B-group vitamins within a given period of time postinfarct enhanced antioxidant capacity and mitigated oxidative damage in stroke disease. No additive or synergistic effects of antioxidants and B-group vitamins together on any outcome measure were reported. All vitamin supplement groups reduced tissue inflammation [250].

COX-2 inhibitors, NS-398 and nimesulide, were also demonstrated neuroprotective after transient and permanent ischemia. Of interest in these studies is that NS-398 and nimesulide are still efficient when their administration was delayed until 24 h after ischemia [266, 267]. On the one hand, these results provide strong evidence that COX-2 may play an important role in the delayed progression of the postischemic lesion, and on the other hand, they suggest that COX-2 inhibition might represent an interesting therapeutic strategy in stroke treatment at the late phase of the damage, although it is not clear when COX-2 is induced in the progression of human cerebral infarction.

Pharmacological studies in animals showed that antioxidant molecules able to cross the blood-brain barrier, such as polyethylene glycol-conjugated superoxide dismutase and catalase [268] and lazaroids [269] reduce ischemic cerebral damage. Finally, transgenic mice overex-

pressing SOD have reduced infarct size compared with wild-type mice [270] while SOD knockout mice have an increased infarct size compared with controls [6].

CONCLUSIONS

Stroke is a major cause of morbidity and mortality among western people. Since the majority of stroke cases are non fatal, its major burden is long-term disability. ROS have been implicated in brain injury after ischemic stroke. Indeed, after vessel occlusion occurs mechanisms merge into a vicious circle accounting for increased ROS production and neuron injury. Most patients do not reach medical facilities early enough for conventional reperfusion strategies, which is the cornerstone of stroke management nowadays. Therefore, therapies targeting patients who cannot undergo thrombolysis must be considered to diminish stroke consequences.

The use of conventional therapies has yielded insufficient results in terms of outcome in stroke patients. Thus, the potential use of unconventional therapies, such as antioxidant defense system enhancement, might play a key role in the management of this disease. Indeed, considering the time course of ROS production, a combined therapy considering both inhibition of ROS-producing enzymes and increased non-enzymatic antioxidant delivery to neurons is expected to effectively diminish brain injury and improve the outcome of these patients. As it can be seen in the schematic approach to antioxidant enhancement proposed on figure 2, this sort of therapy is extensive to a larger period of time compared to reperfusion, widening the amount of eligible patients.

Antioxidant defense system enhancement constitutes a safe, low-cost and widely applicable therapy for stroke patients. Taking into account the promising beneficial effects of this therapy as well as its safeness and low-cost, it emerges as a highly cost-effective alternative for that 97% ischemic stroke patients not receiving reperfusion therapy. Further randomized, double blind, placebo-controlled clinical trials are still lacking to fully establish the usefulness of this scheme.

Chapter 40

MECHANISMS UNDERLYING ISCHEMIC STROKE PREVENTION BY TEA (*CAMELLIA SINENSIS*)

Yuri N. Clement*

Pharmacology Unit, Faculty of Medical Sciences, University of the West Indies, St.
Augustine, Trinidad & Tobago

ABSTRACT

Some prospective cohort and case-control studies suggest that long-term consumption of tea is associated with a reduced risk of mortality from ischemic stroke. Habitual tea consumption is also associated with a reduced risk of developing hypertension (an important cardiovascular risk factor for ischemic stroke). In stroke-prone spontaneously hypertensive rats, green tea consumption attenuated increases in blood pressure which corroborated with human observational studies. Tea flavonols enhance endothelial function by increasing cerebral blood flow and protecting against oxidative stress-induced ischemia. Green tea extract and its putative flavonol, epigallocatechin gallate (EGCG), significantly reduce infarct size in surgically-induced ischemic stroke in animal models. In vivo experiments show that EGCG, a potent free radical scavenger, activates endogenous antioxidant systems which reduce oxidative stress and ameliorate the sequel of events which lead to cerebral ischemia. EGCG reduces neuronal damage caused by chemically-induced oxidative stress, thus providing protection against ischemic stroke in in vitro models. Other studies have suggested that EGCG activates Nrf2 (a transcription factor which stimulates intracellular antioxidant signalling pathways) and increases the activity of heme oxygenase-I (a potent antioxidant enzyme). These mechanisms may explain, in part, the neuroprotective role of green tea against ischemic stroke. At the molecular level, components of green tea may provide neuroprotection by regulating various receptors, including GABA_A, and modulating intracellular signalling pathways, including STAT-1. The evidence from both pre-clinical and clinical studies suggests that tea may prevent ischemic stroke.

INTRODUCTION

For thousands of years, tea (*Camellia sinensis*) has been one of the most popular beverages in Asian countries and its habitual drinking has been attributed to the prevention of many diseases, from various types of cancer to hypertension to obesity [1]. Health benefits also include the prevention of cerebrovascular events, including ischemic stroke [2,3]. The leaves of green tea contain hundreds of natural compounds, and the putative active compounds have been identified as polyphenolic flavonoid antioxidants, known as catechins. Catechins include epicatechin (EC), epigallocatechin (EGC), epicatechin-3-gallate (ECG) and the major flavonoid (-)-epigallocatechin-3-gallate (EGCG)[4]. These antioxidants constitute about one-third of the dry weight of green tea; and the major catechin EGCG has been extensively studied to determine its biological properties. Black tea is processed differently and the fermentation process converts catechins to more complex polyphenols, including theaflavins and thearubigins. Tea polyphenols have been touted as potent antioxidants which may explain their reputed health benefits.

Ischemic stroke occurs when there is a sudden diminution in the blood supply to the brain. Narrowing of arteries supplying cerebral tissue is accomplished by endothelial dysfunction and atherosclerotic plaque build-up which play major roles in the development of cerebrovascular ischemic events. Also, the narrowing of the carotid artery, the formation of blood clots on ruptured plaques, which may break off and form emboli, all contribute to the dramatic reduction in cerebral blood supply and precipitate ischemic stroke. It is proposed that polyphenols found in black and green tea prevent the incidence of ischemic stroke by reducing LDL-cholesterol levels, oxidative stress by direct and indirect mechanisms, LDL oxidation and key inflammatory events which lead to endothelial dysfunction, atherosclerosis initiation and propagation and plaque formation.

In this chapter the evidence regarding the preventive benefits of green and black tea in ischemic stroke is presented based on the findings of epidemiological studies, interventional studies which use standardized extracts in randomized controlled clinical studies, isolated tissue preparations, *ex vivo* models, *in vitro* cell lines and animal models of disease. The molecular mechanisms underlying the preventive effects are also presented. However, much of the research has focussed on green tea, its standardized extracts or its major catechin, EGCG.

CLINICAL EVIDENCE OF ANTIOXIDANT EFFECTS

Oxidative stress is characterized by the accumulation of reactive oxygen species (ROS) [5] which triggers intracellular events leading to protein, DNA and lipid damage [6]. It has been shown that there is a significant increase in ROS in patients with ischemic stroke [7]. Oxidation of LDL-cholesterol plays a pivotal role in the initiation and propagation of atherosclerosis, plaque development and the occurrence of subsequent cardiovascular and cerebrovascular events [8,9], such as ischemic stroke. It has been shown that habitual green tea consumption increases plasma antioxidant status and reduces free radical-induced markers of lipid peroxidation [10].

An open-labelled randomized controlled study demonstrated that the habitual drinking of green tea increased plasma antioxidant power, measured by the ferric reducing/antioxidant power (FRAP) [11]. These results were further supported by a cross-over design study including 21 healthy volunteers who were given black and green tea with or without milk as a single dose [12]. This study showed that there was substantial absorption of catechin, measured by the detection of catechin-related phenolic compounds in the urine of volunteers. In another open-labelled randomized controlled trial volunteers were given 2 cups of green tea (250mg total catechin) for 42 days. There was an increased antioxidant status in these volunteers with a significant reduction in plasma peroxides and decreased induction of DNA oxidative damage in isolated lymphocyte [13].

Another study showed that drinking 6 cups of green tea for 6 months significantly increased antioxidant status and reduced oxidative stress-related toxicities in fuel pump workers exposed to benzene [14]. In this study, green tea abolished the benzene-induced depletion of plasma glutathione and erythrocyte antioxidant enzyme levels. In yet another open-labelled controlled study, which included 14 healthy men, the consumption of green tea (6g in 600mL water daily for 7 days) increased both plasma glutathione levels and FRAP, as well as ameliorated the post-exercise increase in lipid hydroperoxidase [15].

MOLECULAR MECHANISMS UNDERLYING ANTIOXIDANT EFFECTS

Oxidative stress increases the expression of transcription factors, including redox-sensitive Nrf2, which activate intracellular signalling pathways and increase the expression of antioxidant and detoxifying enzyme systems. Nuclear translocation of Nrf2 results in its binding to anti-oxidant response element (ARE-) on the promoter regulatory sites of antioxidant/Phase II detoxifying genes. Wu and colleagues [16] showed that EGCG caused an induction of heme-oxygenase (HO-1) expression in an endothelial cell culture via the up-regulation of phosphatidylinositol 3-kinase (PI3K) and extracellular signal-regulated kinase 1/2 (ERK1/2). EGCG facilitated the nuclear translocation of Nrf2 and subsequent binding to ARE sites of antioxidant genes. This finding was further corroborated in a more recent study where EGCG was shown to induce the expression of antioxidant enzymes HO-1 and manganese superoxide dismutase (MnSOD). This was facilitated by the nuclear translocation of Nrf-2 to ARE promoter regions in human mammary epithelial cell cultures [17]. The researchers also demonstrated that Nrf-2 may possibly be phosphorylated by Akt and ERK1/2 protein kinases prior to nuclear translocation in the signal transduction pathway.

Besides HO-1 and MnSOD, EGCG regulate several other antioxidant and detoxifying enzymes via intracellular signalling pathways which are also mediated by Nrf2. In *in vivo* and *in vitro* models EGCG has been shown to induce antioxidant enzymes including glutathione s-transferase, glutathione peroxidase and catalase [18].

In the vascular endothelium, nicotinamide adenine dinucleotide phosphate (NADPH) oxidase has been identified as a major source of reactive oxygen species. It was shown that both black and green tea polyphenols suppressed the expression of specific subunits of NADPH oxidase, while decreasing oxidative stress in bovine carotid artery endothelial cells [19]. Additionally, black and green tea polyphenols induced the expression of catalase, a

potent endogenous antioxidant enzyme. The generation of reactive oxygen species by NADPH oxidase is closely linked to the inflammatory response, and more recently, it was shown that EGCG blunted the generation of ROS by inhibiting NADPH oxidase in a mast cell line, thus preventing degranulation and release of inflammatory mediators [20].

CLINICAL EVIDENCE OF ISCHEMIC STROKE PREVENTION

A large prospective cohort study in Finland, involving 26,556 middle-aged to elderly male smokers, with an average follow-up of 13.6 years showed that the habitual drinking of more than two cups of green tea daily protected against ischemic stroke, despite the known cerebrovascular risk factor [21]. In another study, which included 6358 Japanese men and women with an average follow-up of 10 years, it was shown that habitual green tea consumption consistently lowered the risk of ischemic stroke and cerebral infarction [22].

A large matched case-control study, involving thousands of Chinese men, showed that regular tea consumption provided protection against the occurrence of ischemic stroke [23]. This was further supported by a smaller case-control study, involving 838 Chinese men, which also showed that habitual drinking of green or oolong tea was inversely associated with the incidence of stroke [24]. The authors of this study also found that besides long-term consumption, that increased daily intake provided additional protection against stroke.

A recent review of the totality of the observational epidemiological evidence, which included seven prospective cohort studies and three case-control studies, suggests that habitual tea drinking provides protection against the occurrence of ischemic stroke [25]. A meta-analysis of nine case-control studies involving 194,965 persons showed that there were significant reductions in the risk of stroke, which increased in individuals consuming three or more cups of tea daily [26].

ANIMAL MODELS OF ISCHEMIA AND MOLECULAR MECHANISMS

Theaflavin, a polyphenol isolated from black tea, decreased infarct volume in an ischemic mouse model. In this model the middle cerebral artery was occluded for two hours and reperfusion over the next 24 hours and theaflavin was shown to modulate the ischemia-induced inflammatory process [27]. It was demonstrated that signal transducer and activator of transcription-1 (STAT-1), a signal transducer and activator of transcription proteins linked to various inflammation-related genes, was down-regulated by theaflavin. Theaflavin-induced inhibition of STAT-1 caused a down-regulation of inflammation-related adhesion molecules (ICAM-1) and reduced the activity of pro-oxidant enzymes (COX-2 and iNOS). These molecular events would lead to reduced inflammation and oxidative stress in the acute ischemia and could explain the reduced cerebral infarct volume in the animal model.

It was also demonstrated that theanine, a green tea polyphenol, reduced cerebral infarct size and altered the expression of biochemical markers of ischemia/reperfusion. It was shown that theanine modulated several molecular pathways which utilize gamma-aminobutyric acid_A (GABA_A) receptors and altered the expression of several genes to provide neuroprotection in this animal model [28]. A more recent study in an experimental model of ischemic stroke in

the mouse showed that the green tea extract, epicatechin, significantly reduced both the extent of cerebral infarction and neurological damage when given before or shortly after reperfusion [29]. Epicatechin caused an up-regulation of transcription factor Nrf2 and increased activity in the antioxidant enzyme heme oxygenase-1 (HO-1) activity and these events may be important in providing protection against ischemic damage.

A cascade of inflammatory events occurs at the onset of ischemic stroke, such as the increased expression of intracellular adhesion molecule-1 (ICAM-1), inducible nitric oxide synthase (iNOS) and cyclooxygenase-2 (COX-2), which promotes macrophage recruitment, production of inflammatory mediators and oxidant-triggered endothelial dysfunction. Theaflavin decreased infarct volume by suppressing the expression of ICAM-1, iNOS and COX-2, by the inhibition of STAT-1. Similarly, ECGC was used in a rat model which showed that there was an inhibition of the ischemic/reperfusion-induced activation of STAT-1 [30]. It was also shown that ECGC inactivated STAT-1 by specifically binding to the phosphorylation site on STAT-1, blocking down-stream signalling pathways responsible for the transcriptional induction of pro-inflammatory mediators.

CLINICAL EVIDENCE OF ANTIHYPERTENSIVE EFFECTS

Hypertension is a major risk factor for the development of ischemic stroke. Hypertension increases the likelihood of endothelial dysfunction and accelerates the events leading to atherosclerotic initiation and progression. The habitual drinking of green tea has been proposed to reduce the risk of hypertension and hypercholesterolemia which are major risk factors associated with the development of ischemic stroke.

A meta-analysis of five randomized-controlled trials including 343 volunteers (some of which were hypertensive) showed that drinking green tea regularly for at least four 4 weeks produced a statistically significant reduction in blood pressure [31]. A larger meta-analysis including 9 studies, which included 4,378 stroke incidents among 194,965 individuals, showed that drinking more than 3 cups of green tea on a daily basis significantly reduced the risk of ischemic stroke [32].

An observational study in 1507 newly diagnosed hypertensive patients (without a history of hypertension over the last 10 years) showed a protective effect in habitual green tea drinkers [33]. A large observational study including 40,530 persons in Japan followed for up to 11 years also demonstrated a significant risk reduction in cardiovascular disease, including stroke, with habitual green tea consumption [34,35]. More recently, a 5-year follow-up observational study in 6,358 individuals demonstrated that green tea consumption significantly reduced the risk of stroke in a dose-dependent manner [22].

A randomized controlled trial involving 110 healthy subjects given a standardized green tea extract twice daily demonstrated significant reductions in cardiovascular risk factors, including blood pressure, LDL cholesterol and oxidative stress over a 3-month period [36]. A small open-labeled randomized crossover study in 20 healthy male smokers showed that the consumption of 400mL of green tea induced immediate reversal of endothelial dysfunction as measured by forearm blood flow [37].

CLINICAL EVIDENCE OF ANTI-HYPERCHOLESTEROLEMIA EFFECTS

An open-labelled randomized controlled study lasting 42 days showed that the consumption of two cups of green tea (250mg catechins) caused a modest, but significant, reduction in LDL cholesterol [13]. Another study was conducted over 24 weeks and had a stratified randomized placebo-controlled trial design. In this study, 40 overweight Japanese children who consumed either green tea (containing 576mg catechin) or placebo and it was demonstrated that green tea produced a significant reduction in LDL cholesterol [38]. Another randomized-controlled trial with 111 participants given either a standardized green tea extract or placebo showed that green tea produced a significant decrease in both total and LDL cholesterol in volunteers with initial elevated LDL cholesterol [36]. A meta-analysis of four interventional studies showed that green tea flavonoids caused a reduction in LDL cholesterol [39].

A randomized controlled study in 40 healthy volunteers showed that the daily intake of 400mg catechin (equivalent to 6-7 cups of green tea) caused a significant reduction in oxidized LDL, a major player in the initiation of atherosclerosis, although there were no effects on the overall lipid profile [40]. Subsequently, a small open-labeled crossover study in 5 healthy females showed that the consumption of 4.5g daily of ground green tea over 2 weeks significantly reduced the susceptibility of LDL oxidation *ex vivo* [41].

In a small study including 12 healthy volunteers the daily consumption of 600mL of green tea over four weeks had no effect on lipid profile, total antioxidant capacity or on markers of inflammation [42]. However, the levels of oxidized LDL and soluble vascular cell adhesion molecule-1 (sVCAM-1) were significantly reduced.

A study using cultured human liver (HepG2) cells showed that EGCG lowered LDL levels by promoting an increase in LDL receptor density and binding activity by modulating gene expression [43]. The green tea polyphenol also induced sterol regulatory binding protein-1 (SREBP-1) activity, which modulates intracellular metabolism of cholesterol.

ANIMAL MODELS OF HYPERTENSION AND MOLECULAR MECHANISMS

Black and green tea intake over three weeks attenuated blood pressure increase in stroke-prone spontaneously hypertensive rats, by reducing oxidative stress and levels of plasma nitric oxide [44]. Furthermore, green tea produced an increase in protein expression of the antioxidant enzyme catalase. It was shown that both black and green tea caused an inactivation of myosin light chain, which plays a pivotal role in vascular smooth muscle contraction and increase vascular resistance, and this may be key in the attenuation of blood pressure rise. The consumption of green tea extract from an early age in malignant stroke-prone spontaneously hypertensive rats significantly reduced the rate of blood pressure increase over time and delayed the onset of spontaneous stroke [45].

Angiotensin II (Ang-II), a potent endogenous vasoconstrictor, causes oxidative stress at high levels and it is implicated in endothelial dysfunction associated with the development of hypertension and atherosclerosis. Rats given green tea extract in their drinking water and injected with Ang-II over 13 days were less likely to develop hypertension [46]. It was shown

earlier that EGCG inhibited Ang-II-induced vasoconstriction by inhibition of the c-Jun N-terminal kinase (JNK) signalling pathway involved in the transcriptional regulation and post-translation modification of mediators which regulate vascular tone [47].

MECHANISMS UNDERLYING EFFECTS IN THE INITIATION AND PROPAGATION OF ATHEROSCLEROSIS

The initiation and propagation of atherosclerosis is a complex inflammatory process commencing with vascular injury, exposure of endothelium accompanied by adhesion and migration of monocytes into the intima. Oxidized LDL-cholesterol play a major role as macrophages are transformed into foam cells. The concerted interactions between transcription factors, intracellular signalling pathways and numerous pro-inflammatory cytokines, adhesion molecules and chemotactic molecules are vital to the formation of atherosclerotic plaques. These events further promote atherosclerotic progression resulting in endothelial dysfunction and plaque formation [48]. Theoretically, antioxidant polyphenolic compounds found in black and green tea should reduce LDL cholesterol oxidation and attenuate atherosclerotic plaque formation to thwart long-term cerebrovascular events, such as ischemic stroke.

The lecithin-like oxidized low-density lipoprotein receptor-1 (LOX-1) is the primary receptor for oxidized LDL in the vascular endothelium, and its activation induces intracellular signals leading to the cascade of pro-inflammatory events. Recently, it was shown that EGCG significantly suppressed the expression of LOX-1 receptors at the transcriptional level in human umbilical vein endothelial cells. This causes the subsequent suppression of intracellular signals, mediated by the redox-sensitive transcription factor NF- κ -B, which up-regulates the expression of pro-inflammatory genes and cell adhesion molecules [49]. It was also shown that protein kinases, p38 MAPK and Ark, responsible for the activation of NF- κ -B were inhibited in the presence of EGCG.

Monocyte chemotactic protein-1 (MCP-1) plays an important role in the migration, adhesion and infiltration of monocytes to the site of vascular injury in the initiation and propagation of atherosclerosis. This cytokine also plays a key role in medial thickening at the site of atherosclerotic lesions. In a randomized clinical trial, involving 30 otherwise heavy smokers, high dose green tea (580 mg catechins daily) over two weeks produced a significant decrease in MCP-1 [50].

Pre-treatment with EGCG inhibited phorbol 12-myristate 13-acetate (PMA)-induced MCP-1 expression and transcription in endothelial ECV304 cells. It was also shown that EGCG inhibited the expression of transcription factors NF- κ B and AP-1, which regulate the expression of MCP-1 and several pro-inflammatory cytokines [51]. An *in vitro* study using a human umbilical vein endothelial cell line showed that EGCG inhibited the expression of vascular cell adhesion molecules (VCAM-1) induced by the pro-inflammatory cytokines TNF- α and IL-1 β [52]. Recently, another study using the human monocyte cell line THP-1 showed that EGCG suppressed the gene expression of both monocyte chemotactic protein-1 (MCP-1) and monocyte cell surface receptors which facilitate migration of monocytes in the arterial wall [53]. It was also shown that EGCG inhibited the cell surface expression of activated β 1 integrin adhesion molecules.

Tumour necrosis factor- α (TNF- α) is an important pro-inflammatory cytokine with a central role in the complex processes in atherosclerotic plaque formation, and EGCG was shown to inhibit TNF- α -induced production of MCP-1 in an endothelial cell culture [54]. It was also demonstrated that EGCG inhibited the phosphorylation of the downstream protein kinase Akt in the intracellular signalling pathway.

Oxidized LDL-cholesterol trapped in vascular endothelium triggers a cascade of inflammatory processes mediated by the pro-inflammatory transcription factor NF- κ B. A recent study showed that green tea polyphenols blocked the oxidized LDL-induced up-regulation of NF- κ B and inhibited the pro-inflammatory cytokine TNF- α production in human umbilical vein endothelial cells [55].

EGCG decreased the vascular endothelial expression of fractalkine, an adhesion molecule and chemoattractant involved in the initial stages of atherosclerosis, in human umbilical vein endothelial cells stimulated with TNF- α [56]. It was shown that down-regulation of fractalkine was mediated by suppression of NF- κ B.

EFFECTS OF TEA POLYPHENOLS ON INFLAMMATORY CYTOKINE PRODUCTION IN ATHEROGENESIS

Besides being a lipid disorder, it is now well established that atherosclerosis is a chronic inflammatory disease. Several pro-inflammatory mediators, known as cytokines, are pivotal in the initiation and maintenance of the inflammatory atherosclerotic state [57]. The pro-inflammatory cytokine interleukin-12 (IL-12) is involved in the early response to stimuli and forms a bridge between innate and adaptive immunity and plays a key role in atherogenesis. It was demonstrated that green tea catechins, particularly EGCG, inhibited the bacterial lipopolysaccharide-induced IL-12 production in murine peritoneal macrophages and a macrophage cell line [58]. This was facilitated by suppression of upstream intracellular pathways, including inhibition of p38 MAPK, which activate and promote the subsequent DNA binding of NF- κ B to promoter regions of other pro-inflammatory cytokines.

Tumor necrosis factor- α (TNF- α) is a potent pro-inflammatory cytokine which plays a pivotal role in augmenting the inflammatory response via the intracellular transcription factor NF- κ B. It was demonstrated the EGCG inhibited lipopolysaccharide-induced TNF- α gene expression and protein production in macrophage cell cultures by blocking the activation of the pro-inflammatory transcription factor NF- κ B [59]. It was further elucidated that EGCG inhibited NF- κ B nuclear translocation, and subsequently increased the expression of pro-inflammatory proteins, by suppressing upstream signalling events involving the cytosolic inhibitory protein I κ B[60]. Also, EGCG was shown to inhibit phorbol 12-myristate 13-acetate (PMA)-induced production of pro-inflammatory cytokines TNF- α , IL-6 and IL-8 in a human mast cell line [61]. EGCG prevented the activation of NF- κ B and ERK1/2 in pro-inflammatory intracellular signalling pathway.

In monocytes, isolated from human blood, it was shown that green and black tea extracts inhibited the lipopolysaccharide-induced expression of the pro-inflammatory cytokines IL-1 β , IL-6, IL-8 and TNF- α and prostaglandin E₂ [62]. These researchers also showed using a macrophage cell line that both tea extracts inactivated NF- κ B via inhibition of proteasome function. Another study showed that there was a transcriptional induction of IL-6 in a

macrophage cell line incubated in the sera of normocholestraemic hypertensive individuals [63]. This study provided the evidence that hypertension induces mechanisms which attenuates inflammatory processes linked to the initiation of atherosclerosis.

EFFECTS OF TEA POLYPHENOLS ON VASCULAR ENDOTHELIUM FUNCTION

Persistent endothelial dysfunction, caused by oxidative stress, is crucial in the pathogenesis of atherosclerotic plaques which eventually progress to events such as ischemic stroke and myocardial infarction. It has been proposed that polyphenols in tea affect vascular endothelium function by improving blood flow which increases and maintains cerebral perfusion which would prevent ischemic stroke [64].

In a randomized cross-over trial it was demonstrated that green tea caused an acute increase of almost 4% in flow-mediated dilatation of the brachial artery [65]. Smoking is the most important risk factor for the development of atherosclerosis and a recent randomized controlled study showed that daily consumption of high dose green tea catechins (580 mg) for two weeks in heavy smokers produced a significant improvement in acetylcholine-mediated endothelial responsiveness in the forearm following acute and chronic dosing [50]. The investigators also demonstrated that green tea at the high dose increased levels of the endogenous endothelium-derived vasodilator nitric oxide.

MECHANISMS UNDERLYING THE EFFECTS OF TEA ON ENDOTHELIAL FUNCTION

In spontaneously hypertensive rats EGCG given over a three-week period attenuated the rise in systolic blood pressure by improving endothelial dysfunction [66]. Earlier it was shown that EGCG produced an endothelium-dependent vasodilation caused by an increase in endothelial-derived nitric oxide synthase (eNOS) activity via activation of Akt and protein kinase A (PKA) in bovine aortic endothelial cells [67]. Similarly, EGCG was shown to induce eNOS in *ex vivo* mesenteric vascular beds and bovine endothelial cells [68]. These experiments indicate that EGCG in the presence of reactive oxygen species and Fyn utilized intracellular signalling pathways which led to the activation of phosphatidylinositol 3-kinase (PI-3), Akt and eNOS. Extracts from both black and green tea stimulated eNOS activity in bovine aortic endothelial cells and produced significant relaxation of isolated rat aortic rings [69]. Green tea catechins decreased endothelial exocytosis, the initial inflammatory step in atherogenesis, by attenuating monocyte adhesion to vascular endothelial and increased nitric oxide by enhancing eNOS activity [70].

Caveolin-1 negatively regulates the expression of eNOS, and it was shown that green tea polyphenols down-regulated the expression of this regulator in bovine aortic endothelial cells [71]. This down-regulation, which caused an increase in eNOS expression, was facilitated by the activation of ERK 1/2 and inhibition of p38MAPK signalling pathways.

On the other hand, related to atherosclerosis, the expression of inducible nitric oxide synthase (iNOS) promotes the production of inappropriate levels of nitric oxide which

initiates a vascular immune response to activated macrophages. In another study, EGCG blocked the angiotensin-II-induced expression of iNOS in human umbilical vein endothelial cells [72]. An earlier study using cancer cell lines showed that EGCG down-regulated the both the expression of iNOS mRNA and protein, as well as nitric oxide production, by suppressing the activation of STAT-1 α transcription factor [73].

CONCLUSIONS

Tea has been one of the most popular beverages for millennia and many health benefits have been attributed to its antioxidant effects. Many observational and interventional studies have shown that regular tea consumption over the long term has beneficial effects in lowering cardiovascular risk factors, such as blood pressure and LDL-cholesterol levels, and improve endothelial function. These are important biochemical and physiological factors which contribute to atherosclerotic development and the occurrence of cerebral ischemia.

Catechins and theaflavins are important antioxidant polyphenolic compounds identified in green and black tea respectively. Although these antioxidants act directly to scavenge reactive oxygen species they also trigger other molecular mechanisms which enhance their antioxidant activity. Tea polyphenols activate intracellular signalling pathways utilizing the redox-sensitive Nrf2 transcription factor and a complex network of protein kinases. This interaction up-regulates the expression of potent endogenous antioxidant enzymes, including catalase and heme oxygenase-1, and blunts other signalling pathways which enhance the production of reactive oxygen species.

Tea polyphenols reduce the oxidation of LDL-cholesterol, which is a key component in the development of atherosclerotic plaque formation, and blunt inflammatory processes necessary for initiation and propagation of atherosclerosis. In *in vitro* studies it has been demonstrated that tea polyphenols attenuated many processes necessary for monocyte attraction, adhesion and migration at the site of injury on the vascular endothelial. In experimental models catechins suppress the release of chemoattractants, pro-inflammatory cytokines and adhesion molecules by complex intracellular mechanisms which utilize the pro-inflammatory NF- κ B transcription factor.

Catechins have also been shown to improve endothelial function by causing vascular relaxation. This activity would be beneficial to increase blood flow and reduce the likelihood of ischemia. Experimental models show that catechins cause vasodilatation by increasing endothelial nitric oxide concentrations via induction of endothelial-derived nitric oxide synthase (eNOS). Tea catechins activate intracellular signalling pathways which utilize a complex series of protein kinases which up-regulate the expression of eNOS.

Although most *in vitro* and *in vivo* studies indicate biological activity and the modulation of various intracellular signalling pathways, it must be borne in mind that most of these experiments use tea polyphenol concentrations much higher than that which could be achieved by moderate tea consumption.

Chapter 41

NEONATAL ASPHYXIA AND STROKE: MORBIDITY, MODELS, CONSEQUENCES, AND TREATMENTS

J. R. Rivers and J. C. Ashton

Department of Pharmacology and Toxicology,
University of Otago, Dunedin, New Zealand.

ABSTRACT

Neonatal and early childhood asphyxia is a major cause of morbidity and chronic cognitive dysfunction. In developed countries approximately births per 1000 have asphyxia related complications including encephalopathy.

In this chapter we will discuss the burden of neonatal asphyxia and stroke, and the neurological consequences to the individuals afflicted, including epilepsy, cerebral palsy, and cognitive impairment.

At present, treatment is focused on managing the symptoms of perinatal asphyxia. As new treatments are clearly needed, various models have been developed to test putative neuroprotectants.

We discuss the strength and limitations of each of the most commonly used animal models.

We finish with a discussion existing treatments for acute care, including hypothermia, and the most promising pharmacological candidates for clinical use.

1. INTRODUCTION

1.1. Peri/Neo-Natal Hypoxia and Hypoxia Ischemia

Hypoxia is pathologically low blood oxygen levels (Bracci, Perrone, and Buonocore, 2006) and ischemia is disruption in blood flow. Ischemia due to the occlusion of a blood vessel in the brain results in a stroke; a cascade of neuronal death that is extremely common in aging adults (del Zoppo, 1998). Given that the damage caused by ischemia is the result of hypoxia, why are the two terms used to describe some types of ischemia but not others? Why

is the designation “hypoxia ischemia” most often associated with neurological damage in newborns, either around the time of birth (perinatal) or recently after birth (neonatal)? The answer is in the history of research into neonatal hypoxia, a condition in which ischemia causes not only local hypoxia but also global hypoxia throughout the fetus. The fetus relies on nutrients and oxygen supplied through blood vessels of the umbilical cord, which can become compressed during birthing complications and cause ischemia of the umbilical cord, resulting in global hypoxia of the fetus and damage to sensitive organs (Satas, et al., 2003). The brain is injured significantly more than other organs and these effects are lasting with significant effects of quality of life (Gunn, Gunn, deHaan, Williams, and Gluckman, 1997; Hopkins-Golightly, Raz, and Sander, 2003). The pathology is very similar to that caused by local ischemia in the brain (stroke) (Comi, Weisz, Highet, Johnston, and Wilson, 2004). This unique combination of ischemia and global hypoxia gave rise to the field of hypoxic ischemia in the peri/neo-natal period of life. This chapter will discuss the properties of peri/neo-natal hypoxia ischemia with respect to neuro-pathology, the animal models used to investigate this pathology, and potential interventions and pharmacological treatments that are under development.

1.1.1. Hypoxia Ischemia Prevalence and Risk Factors

Peri/neo-natal hypoxia is a pathological drop in oxygen levels in an infant’s blood, often caused by compression of the umbilical cord or asphyxia due to birthing complications or a choking incident (Lawn, Shibuya, and Stein, 2005). In 1997 it was estimated by the World Health Organisation (WHO) that 19% of the 5 million infant deaths that year were caused by hypoxia related condition (Shiffman, 2010). The most prevalent birthing complication that results in hypoxia ischemia is nuchal cord; this involves the umbilical cord forming a loop around the neck of the fetus, and has been linked to an increase in perinatal mortality. During nuchal cord the umbilical cord can become compressed, blocking the supply of oxygenated blood to the fetus. This can cause acidosis of the fetal blood and hypercarbia (Hankins, Snyder, Hauth, Gilstrap, and Hammond, 1987). Nuchal cord occurs in 8-34.5% of births, with around 5% of all births having a “tight” nuchal cord (Ogueh, et al., 2006). Due to advances in intrapartum care most of these cases are asymptomatic. A study by Ogueh et al. (2006) analyzed data from 57,873 births and found that tight nuchal cord incidents resulted in lower birth weights, longer birthing times, increased incidences of shoulder dystonia, and increased cesarean intervention. These are often associated with ischemia and encephalopathy (Bloch, 2005).

In the developed world the incidents of such complications have decreased dramatically over the last three decades. In Canada between 1991 and 2004 the rate of hypoxia ischemia related complications dropped from 43.8 to 2.4 cases in every 1000 births (Dzakpasu, et al., 2009). This decrease is due to improved care with a rise in the use of fetal heart monitoring systems (cardiotocography) and induced labor and caesarian births (Smith, Wells, and Dodd, 2000). In the developing world such data is difficult to acquire as stillbirths (including hypoxia related deaths) are often not reported and no birth or death certificate is generated. However it is likely that the rate of asphyxia related complications is much higher than that of developed countries (Lawn, et al., 2005).

Stroke is a disruption in the blood flow within the brain. This can be caused by a thrombus (ischemic stroke) or a rupture of a cerebral blood vessel (hemorrhagic stroke). Stroke during the perinatal and neonatal period was previously thought to be a relatively rare

pathology, but recent evidence has suggested a far greater prevalence. Peri/neo-natal stroke has gone unnoticed due to plasticity of the neonatal brain. Because of the recent emergence of this field and because of the physiological similarity to the hypoxia ischemia, peri/neo-natal stroke has come under the research umbrella of hypoxia ischemia, sharing many animal models and putative therapies. Lynch et al. (2002) reviewed perinatal stroke which they defined as the developmental period between 28 weeks gestation to 28 days postnatal age and calculated the incidence of symptomatic perinatal stroke to be 1 in every 4000 births in the developed world. However, the authors report that because of the difficulty of diagnosis due to difficulty in assessing newborns for neurological function, the incidence of symptomatic stroke may be higher still. Because stroke can occur in any region of the brain the symptoms are more varied than that of hypoxia ischemia, and include motor deficits, sensory deficits, impairment of memory and cognition, and epilepsy (Kolk, Ennok, Laugesaar, Kaldoja, and Talvik, 2010).

2. CELLULAR PROCESSES OF NEURONAL DEATH DURING ISCHEMIA

2.1. Excitotoxicity

The reduction in oxygen levels and glucose levels in the brain following HI causes disruption in neuronal ATP production. This causes the mechanisms which maintain the cell membrane potential such as Na^+/K^+ ATPase to cease functioning, causing the cell to depolarize and release its neurotransmitters including glutamate (reviewed in (Nishizawa, 2001; J. R. Rivers and Ashton, 2010a; Rothman and Olney, 1987). Increasing concentrations of glutamate in the extracellular space causes excitation of other neurons, primarily through NMDA and AMPA receptors. This not only increases the energy demands of cells in an already energy deprived environment, but also results in pathological levels of Ca^{2+} flux into the neurons. This causes osmotic influx of water resulting in cellular edema that can result in necrosis as well as disruption in mitochondrial function, resulting in apoptosis (Wahlgren and Ahmed, 2004). As the neurons depolarize and undergo necrosis, further glutamate is released resulting in an excitotoxic cascade throughout the brain. This process occurs in both the immature and mature brain. However, recent evidence suggests that NMDA receptors in the developing brain have enhanced function, and that this is crucial for plasticity during development. This increases susceptibility to excitotoxicity in the immature brain (Johnston, et al., 2009). The ability of astrocytes to absorb high levels of neurotransmitters is reduced in the immature brain, with cerebral spinal fluid (CSF) levels of glutamate shown to be heightened in HI affected infants up to 16 hours after the insult (Pu, et al., 2000).

2.2. Reactive Oxygen Species (ROS) and Reactive Nitrogen Species (RNS)

ROS and RNS are highly reactive molecules that can react with cellular components including proteins, fats, and nucleic acids. In the case of proteins this causes a breakdown of cellular process including enzyme function, ion pump function and receptor activity, and can

result in depolarization of the cell, potentially initiating the excitotoxic cascade. In the case of fats such as phospholipids, membranes can become permeable, also resulting in depolarization of the cell and of the mitochondria, causing a loss of energy production. This reaction is especially damaging as the phospholipids auto-catalyze the oxidation of other phospholipids resulting in widespread membrane failure. This can lead to further cellular edema and excitotoxicity. Oxidative damage to nucleic acids can result in mutation and a loss in translational and transcriptional function (Ikonomidou and Kaindl, 2011).

ROS and RNS are continuously produced by cells but are normally in balance with endogenous antioxidant mechanisms that safely catalyze the reactions of ROS and RNS to non-harmful compounds. For example, the highly reactive ROS superoxide reacts with water to form hydrogen peroxide, catalyzed by superoxide dismutase. Hydrogen peroxide is then reduced with oxygen to form water, catalyzed by catalase (Ikonomidou and Kaindl, 2011). A major site of ROS and RNS production is mitochondria. Electrons in the electron transport chain (ETC) normally contribute to a controlled series of reactions, but can become dissociated from the ETC before reaching the critical molecule complex IV, and instead react with other nearby molecules. These uncontrolled reactions form ROS and RNS; for example electron donation to oxygen produces superoxide.

If the balance between ROS, RNS and endogenous antioxidant mechanisms is disrupted, ROS and RNS can react with mitochondrial membrane phospholipids and disrupt the integrity of the membrane. This causes depolarization and a catastrophic reduction in of ATP synthesis. This also causes cytochrome C to leak from the membrane into the cytosol, and act as signaling molecule for apoptosis. During HI, ROS and RNS levels rise beyond antioxidant capacity, and through this pathway cause neuronal apoptosis for days after injury.

In HI, low oxygen levels prevent the donation of the electrons of the ETC, this causes electrons to build up on the ETC and leak from the chain, generating ROS and RNS. Once HI is over, reperfusion produces high levels of oxygen which results in uncontrolled electron donation to oxygen, generating more superoxide and other ROS and RNS. Until recently 100% oxygen was given to infants that had undergone an HI incident. It is now recognized that 100% oxygen may exacerbate reperfusion injury and that normal levels of oxygen may be less harmful (Pu, et al., 2000).

The developing brain is more sensitive to increases in ROS and RNS than the mature brain. One reason for this is because the developing brain has lower levels of antioxidants. One study has show that fetal serum levels of the strong antioxidant tocopherol were 80% lower than that of an adult. Similar deficiencies have been found for other antioxidants such as selenium. The developing brain is also restricted to the extent that it can upregulate antioxidant synthesis or function; for example, glutathione peroxidase and glutathione. Contradicting this however, some evidence suggests that in healthy full term births the ratio of antioxidant to ROS/RNS is greater than that of an adult, perhaps because of adaptive mechanisms that help the newborn adapt to the high oxygen environment outside the womb (Parmigiani, Gianotti, Pezzoni, Corradi, and Bevilacqua, 2011). However, this may not be true for premature infants, which is particularly significant because of the common co-morbidity of premature birth with perinatal HI (Drury, Nycyk, Baines, and Cooke, 1998).

2.3. Inflammation

Under healthy conditions the brain is an immune privileged organ. Specialized glia cells called microglia, which act as the resident immune cell for the CNS, become activated upon the molecular recognition of tissue damage or the presence of pathogens. Once activated microglia secrete proinflammatory cytokines which promote the migration and activation of more microglia and cause the endothelium to express adhesion molecules that allow blood-borne immune cells to infiltrate into the CNS. Once at the site of injury, immune cells produce a cocktail of neurotoxic factors that includes ROS/RN, cytokines, and glutamate.

These diffuse from the immediate site of injury (infarct core) into the surrounding tissues, generating further neuronal death in the proximal healthy tissue (penumbra). Immune cells produce NO from the oxidation of L-arginine to citrulline via various nitric oxide synthase (NOS) enzymes. NO has both vasodilatory and antimicrobial effects, but when produced at pathological levels can cause neuronal damage by the activation of apoptosis pathways and competition for oxygen with cytochrome c (Klegeris, Bissonnette, and McGeer, 2003).

The cytokines produced by microglia and systemic immune cells have been shown to be neurotoxic in many *in vitro* studies (Klegeris, Bissonnette, and McGeer, 2003; Venters, et al., 1999). Cytokines including TNF α and IL1 β induce astrocytes to produce NO via inducible NOS (iNOS) and affect cell signaling pathways involved in neuronal survival and apoptosis (J. K. Lee, Tran, and Tansey, 2009; Venters, et al., 1999). Infections during pregnancy can produce HI-like processes, and evidence suggests that cytokines produced by the mother can have neurotoxic effects on the fetus (Bloch, 2005).

NO produced by activated immune cells and astrocytes induces both the release of glutamate by neurons via depolarization and the inhibition of the reuptake of glutamate by astrocytes (Bal-Price and Brown, 2001; Chao, Hu, Ehrlich, and Peterson, 1995).

Clear evidence of the role of neuroinflammation in neuronal death after has been provided by the use of transgenic mice that lack key proinflammatory cytokines, interleukin 1 β and interleukin 18. The transgenic mice were protected from hypoxic injury compared with wild type controls (Felderhoff-Mueser, et al., 2005).

However, clinical studies of neuroinflammatory diseases, such as meningitis, demonstrate that neuroinflammation can occur without neuronal death, so oxidative injury may be necessary to initiate inflammation that results in neuronal death.

3. BRAIN REGIONS VULNERABLE TO THE EFFECTS OF HYPOXIA ISCHEMIA

3.1. Prenatal and Perinatal Hypoxia Ischemia

The regions and cell types that are most vulnerable to damage change with the development stage of the brain. Prenatal and perinatal HI is associated with white matter injury such as periventricular leukomalacia (PVL) and periventricular white matter injury (PWMI) (Scafidi and Gallo, 2008). The prevalence of PVL and PWMI decreases with increased birth weight and length of pregnancy, with a preterm prevalence of 60 PVL infants per 1000 births compared to a full term prevalence of 1.3/1000 (Bracci, et al., 2006). The

particular stage of cell development and receptor types expressed determines sensitivity to injury.

In prenatal and perinatal HI the insult occurs during production of oligodendrocytes when oligodendrocytes progenitor cells (OPC's) are immature and highly active (Bracci, et al., 2006). During this stage, OPC's express an intermediate form of the AMPA receptor that lacks the GluR2 subunit.

This facilitates higher levels of Ca^{2+} transport, and makes the developing OPC's more susceptible to excitotoxicity (Johnston, et al., 2009). There is also evidence that the OPC's have low levels of antioxidant enzymes (Ikonomidou and Kaindl, 2011).

3.2. Neonatal Hypoxia Ischemia

In a full term infant of normal birth weight, oligodendrocytes production is advanced, but myelination of neurons is still at an early stage. Hypoxia during this period has little effect on the white matter, but does have substantial effects on neurons in the basal ganglia (Rice and Barone, 2000). Neonatal HI causes damage predominately to the putamen and the thalamus, and this can result in cerebral palsy; general non-progressive brain damage that occurs during development and predominately affects motor function. MRI studies suggest that the susceptibility of motor centers is due to high levels of glutamatergic input (Johnston, Trescher, Ishida, and Nakajima, 2001). This is further supported by fMRI studies that show newborns that have HI induced seizures have hyperactive neurons in these regions (Johnston, et al., 2001).

The hippocampi are key structures involved in spatial memory, and are vulnerable during neonatal hypoxia (Bass, et al., 2004). Although studies in humans are limited, it appears that hippocampi are among the first regions to be affected during HI. MRI and functional studies show that children that have undergone HI during or near birth have near normal intelligence with only mild dyspraxia can have severely affected memory and hippocampal volume (Gadian, et al., 2000). Little is known about the processes that cause hippocampal sensitivity despite extensively studies using rodent models of HI, although there is some suggestion that the hippocampus may be a site of intense excitotoxicity (Clarkson, et al., 2005; Gurd, et al., 2002). Complicating matters, these regions may be especially plastic during early development, potentially masking damage from behavioural assessment (Johnston, et al., 2009).

Interestingly, mechanisms of cell death change with development, with a shift from programmed cell death early in development to necrosis in the mature brain (Liu, Siesjo, and Hu, 2004). This suggests that targeting apoptosis for pharmacological intervention may be more successful in the developing brain than in the mature brain (Cowper-Smith, Anger, Magal, Norman, and Robertson, 2008).

4. ANIMAL MODELS OF HYPOXIA ISCHEMIA

Many animal models have been used to study peri/neo-natal HI. The most common animal models use sheep, pig or rodents. A review in 1996 found that 26% of all animal

studies on HI were done using rodent models, with sheep and pig models representing 23% and 22% of the research respectively (Roohey, Raju, and Moustogiannis, 1997). Critically, this review found that 71% of all studies assessed the outcomes of the HI only between 0 and 24 hours after the insult. Recent evidence suggests that disease progression is variable and can last for weeks or months after the initial insult (Kolk, et al., 2010; Vannucci and Vannucci, 2005). This has historically been a shortcoming of animals studies and has only recently started to be addressed (Vannucci and Vannucci, 2005). This section will give a brief description of some of the common animal models, addressing the advantages and disadvantages of each.

4.1. Primate

Primate models have the advantage of close homology to humans. The genetic profiles of the animals are similar to humans as well as the gestational process and development. The complexity of the brain is the most closely related to humans out of any animal model (Roohey, et al., 1997). Primate models normally involve inducing injuries either prior to birth or at birth. This is because brain development is very similar to the human condition so unlike other animal models such as rodent models, the estimated equivalent developmental stage of the fetus at birth is the similar to humans. Two models dominate the primate field; the most common involves cesarean birth where the umbilical cord is occluded for 10 to 15 minutes (Beckstrom, Humston, Snyder, Synovec, and Juul; Juul, et al., 2007). The second model involves warm saline emersion after birth prior to the first breath of the infant (Roohey, et al., 1997). Both models result in very similar histological and behavioral pathological effects to that of the human condition, such that putative therapeutics that have been found to be effective in these models should be strongly considered for human trial.

The limitation of primate models involves expense and accessibility. The cost of primate models and the long gestational periods of the animals constrains experimental numbers, thus the studies are often underpowered. This is a particular problem in animal models of hypoxia, where highly variable outcomes are the norm (Jack R. Rivers, Sutherland, and Ashton, 2011). Ethical issues arise for the same reason that makes non-human primates excellent models of human pathologies. It is likely that these animals have a greater similarity to humans in experiencing suffering and pain than other animals. For this reason experiments on primates are often the target political and social debate, limiting their use in some countries (McNeil, 2008).

4.2. Sheep and Pig

Pigs and sheep are also used in models of peri/neo-natal HI. Both pigs and sheep have similar sized newborns to humans, with comparable stages of brain development and size. These factors result in the oxygen and other metabolic demands of the brain that are similar to humans (Northington, 2006). There are several different methods of inducing HI in these animals. Hypoxia of the pregnant mother and umbilical clamping are common (Northington, 2006). Other methods used are new born asphyxia or carotid artery ligation. These methods have the advantage of not needing anesthesia of the pregnant mothers (Domoki, et al., 2010).

Sheep are more analogous to the human with respect to number of fetuses per pregnancy (1-2), whereas pig litter sizes number from 8-14. Although this is less analogous to humans, large litters reduce costs and therefore can result in more statistically powerful studies. Physiologically, these animals are a good intermediate between rodent studies and non-human primate studies.

There are many limitations of these large animal studies. High costs of care are an issue as well as long developmental and gestational periods. This makes large experiments difficult, and limits the statistical power of studies that involve these animals. Furthermore, the behavior of on these animals is poorly characterised compare with rodents or humans, and the animals develop more quickly than humans, making long term comparisons difficult. Despite this, these models are popular as there are fewer ethical issues compared with primates, and the animals are readily available due to agricultural production.

4.3. Rat and Mouse

Rat and mouse models are the most popular models used in HI. The use of these animals has several advantages. These animals have fast development, are small in size, and are cheap to purchase and maintain, these factors allow for high numbers in a study. This increases the power of the study allowing researchers to study putative protective therapies that may only produce a small improvement in the condition. Furthermore, researchers can study many potential therapies in a relatively short period.

The availability of genetic knockouts and specific phenotypic strains are a further advantage of rodent models. Genetic knockouts allow for the testing of the function of certain genes/proteins during and after HI, as well as facilitating the testing of the specificity of probes used to assay changes in proteins (Chen, et al., 2006). Specific phenotypes, such as spontaneously hypertensive rats, allow the study of co-morbidities which can be common in human conditions (Bloch, 2005).

Using histological analysis such as cellular layering, myelination and neurogenesis, it appears that the development stage that is equivalent to the human at birth is after birth in the rodent is approximately 7 days post birth in both mice and rats (Ten, Bradley-Moore, Gingrich, Stark, and Pinsky, 2003; Vannucci and Vannucci, 2005). Although age correlations differ depending on which histological, behavioral, or physiological aspect is compared (Rice and Barone, 2000). This means the injuries can be induced in pups, without complicated caesarian. Although, some umbilical clamping models are still used in rodent models, by the far the most common models involved ligation of one or more of the blood vessels that supply brain 7 days after birth. Two main models exist: (i.) ligation of both common carotid arteries, leaving only the vertebral arteries to supply blood to the brain. This results in global bilateral damage to the cortex. (ii.) A more common method involves ligation of one of the common carotid arteries followed by a period of hypoxia normally facilitated through a chamber filled with 5-8% oxygen in nitrogen. 7 day old rats normally require 2-3 hours of hypoxia to acutely produce a large unilateral infarction of the cerebrum, mice and older rats require much less time to produce a similar infarct (40-70 mins) (Jack R. Rivers, et al., 2011). The advantage of the latter model is that it leaves an intact hemisphere which allows for histological, biochemical and behavioral comparisons. However, recent evidence now

suggests that the apparent healthy hemisphere may have low levels of damage (Huang, Liu, Cheung, and Chen, 2009).

The shortfalls of rodent model arise from the difference in anatomy and physiology compare with humans. The development of the rodent brain is faster, with adult-like behavioral phenotype reached 20 days after birth in rats. There is therefore a clear gap between these models and clinical applicability. Criticism of preclinical research have increased steadily over the last two decades as therapies found to be effective in preclinical research are failing to produce similar effects in large and expensive phase three clinical trials (Wahlgren and Ahmed, 2004). Some of these criticism focus on the models themselves, questioning the use of models such as rodent ones and whether they produce similar pathological physiological states to those in human conditions (Wahlgren and Ahmed, 2004).

5. TREATMENTS

5.1. Current Clinical Treatments

5.1.1. *Prevention: Pharmacological and Surgical Interventions*

Advances in prenatal and birthing care and diagnostics has seen significant decreases in perinatal HI and improved outcomes after HI (Smith, et al., 2000). Detection of complications such as nuchal cord and maternal infections has increased with greater monitoring during pregnancy. This monitoring includes the use of cardiotocography to monitor the heart rate of the fetus, thus detecting possible causes of global hypoxia such as defibrillation or pathological bradycardia. Also, the use of fetal imaging using color Doppler and ultrasound, can detect if a complication like a tight nuchal cord requires more intense monitoring and possible cesarean birth (Ogueh, et al., 2006).

Oxytocin is a hormone that causes labour induction, and can be administered as a drug to induce labour (Milson, et al., 2002). Inducing labour has lowered the prevalence of HI by inducing birth in cases where the fetus has an acute complication such as bradycardia. Also if the pregnancy has gone on beyond 42 weeks, the size of the fetus increases the risk of birthing complications that are associated with hypoxia during birth (Ogueh, et al., 2006).

5.1.2. *Rehabilitation: Physiotherapy*

Neuroplasticity is the ability of the brain to remodel structurally and functionally. The primary mechanisms of neuroplasticity is changes in the processes of the neurons including dendritic and axonal branching, changes in synapse number, and the formation of new neurons through neurogenesis (Holt and Mikati, 2011). After HI there is a neuroplastic reorganisation process that redistributes function from the damaged areas of the brain to the healthy cortex. In peri/neo natal HI dendritic and axonal branching as well as synaptogenesis is most likely the most important mechanism of neuroplasticity, as in the developing brain a surplus of neurons already exists (Holt and Mikati, 2011).

Neuroplasticity is strongly influenced by activity of the cortex. Pathways that are used and therefore activated more frequently are strengthened and developed. The developing brain is particularly plastic and is therefore better able to recover from injury. Therapies have been successfully developed for after HI that assist the rewiring process that is needed to

maintain normal function. Challenging the affected individual in cognitive and motor tasks is referred to as enrichment, and has been shown to assist in the rewiring process.

Therapies involving increasing the movement of the effected limbs have been shown to be successful in adult stroke, and there is growing evidence that this is also true for peri/neo-natal HI. From stroke studies it appears that several methods are useful, these include the manual assisting of movement of the limbs by physiotherapist in severally disable individuals. Also, constraining the use of unaffected limbs in more able individuals encourages use of the disabled limb. In the only slightly impaired individuals with mild dyspraxia, challenging games can be used, including ball games and precision grip games, to improve daily motor function (Kolk, et al., 2010).

Transcranial magnetic stimulation (TMS) is a strong directional magnetic field applied to the surface of the skin above the target area that induces depolarization of the neurons under the area. When applied at different intensities and frequencies the brain region can be either induced into a hyper-excitabile or a hypo-excitabile state. This is thought to occur through long term potentiation (LTP) and long term depression (LTD) respectively (Holt and Mikati, 2011; Thordstein, Hallbook, Lundgren, van Westen, and Elam, 2011). TMS they can downregulate or upregulate the use of certain brain regions, and so might be used to increase the functionality of a damaged area by facilitating neuroplasticity, including by temporarily arresting function in complementary undamaged brain regions (thereby forcing use of compromised brain regions) (Bernard, Goldenberg, Armstrong-Wells, Amlie-Lefond, and Fullerton, 2008).

5.1.3. Limiting Brain Damage: Pharmacological Intervention

There is no pharmacological intervention for use after peri/neo-natal HI that has completed stage 3 clinical trials (Scafidi and Gallo, 2008; Yager, Armstrong, and Black, 2009). Current pharmacological interventions involve tightly controlling the homeostasis of the infant. The two systems that are most crucial to the infant survival and that must be controlled are carbon dioxide and blood glucose homeostasis. Hypocapnia or low CO₂ levels of the blood are associated with worsened outcomes following HI. Low levels of CO₂ results in vasoconstriction, potentially further reducing oxygenated blood flow to the brain, and increasing brain damage. However, despite excellent preclinical evidence, no clinical evidence exists that maintaining high of CO₂ is neuroprotective. In spite of this it still seems prudent to maintain normal or high levels of CO₂ of ventilated infants following HI. With respect to blood glucose, hyperglycemia has been shown in animal models to be neuroprotective, yet no clinical data exists on glucose related interventions. Hypoglycemia has been associated with poorer outcomes following HI and thus glucose levels are tightly controlled.

Seizure activity is common in the first 72 hours after an HI incident, and rarely afterwards. These seizures are not controlled by anticonvulsants as the potential risks of administering anticonvulsants to the developing brain may outweigh the potential benefits. A metaanalysis of 7 different placebo controlled clinical trials that use anticonvulsants showed no benefit to the clinical outcomes of the infants (Evans, Levene, and Tsakmakis, 2007). Furthermore, seizures may be a symptom of mass neuronal death and may not be involved in exacerbating the damage (Jack R. Rivers, et al., 2011). However, seizures have been associated with an increase in body temperature that will worsening the pathology (Wirrell, Armstrong, Osman, and Yager, 2001). Conversely HI induced epilepsy that continues beyond

infancy must be controlled with antiepileptic to limit continued damage and improve quality of life (Glass and Sullivan, 2009).

5.1.4. Limiting Brain Damage: Hypothermia

Hypothermia can be induced by placing the infant in cold water, or by use of a cold cap on the infants head. Both methods are used to lower the body temperature of the newborn by 3–4°C. Many mechanisms of neuroprotection have been proposed.

Hypoxia reduces rates of reactions and thereby lowers the metabolic demands of cells within the brain; this allows them to operate on a low oxygen and glucose budget. Animal model studies have shown a complete preservation of ATP levels from hypothermia (Yager and Asselin, 1996). This would prevent the loss of function of crucial cellular functions such as Na⁺/K⁺ ATPase and thus maintain membrane potential, preventing excitotoxic cascades and ROS/RNS related damage. The second mechanism could be an immune cell modulation effect. Immune cell function and reactivity is lower in lower temperatures, this could prevent the pathological neuroinflammatory effect seen for days or weeks after HI (Maekawa, et al., 2002). This mechanism could also explain why hypothermia must be maintained in the clinic for the relatively large period of time of 72 hours in order to be effective.

5.2. Putative Pharmacological Treatments

Apart from hypothermia, physical rehabilitation, and preventative surgical and pharmacological intervention, there have been few if any drug treatments that have been proven to be effective at reducing the burden of disability due to neonatal hypoxic encephalopathy. Nonetheless the pharmacological management of peri/neonatal hypoxia is an area of intense research. Treatment strategies can be roughly divided into those that are intended to reduce brain damage either during or subsequent to hypoxia ischemia, and those that are aids to rehabilitation.

5.2.1. Limiting Brain Damage

The pharmacological strategies for reducing brain damage following hypoxia ischemia that have been most intensively investigated can be grouped according to the main elements of the pathological cascade described above; excitotoxicity, oxidative stress, and inflammation. These correspond to drugs that reduce CNS excitation, antioxidant therapies, and anti-inflammatories and other drugs that affect wound healing respectively.

5.2.1.1. Inhibitors of CNS Excitation

Excitotoxicity is fundamentally a property of excessive glutamate signaling, and so antagonists at glutamate receptors have been at the forefront of attempts to reduce brain damage. These include inhibitors at the glutamate NMDA and AMPA receptors. NMDA receptor inhibitors have been extremely successful in a variety of animal model of cerebral ischemia, often causing dramatic reductions in brain damage (Clarkson, et al., 2005; Fernandez-Lopez, et al., 2006). However, this success in preclinical research has not translated into successful treatments in the clinic (Hoyte, Kaur, and Buchan, 2004; Lo, 2008a).

The reasons for this continue to be debated, with quality of preclinical experiments and publication bias cited as a factor (O'Collins, et al., 2011; E. Sena, van der Worp, Howells, and Macleod, 2007; E. S. Sena, van der Worp, Bath, Howells, and Macleod, 2010) along with the inapplicability of animal models and the incompatibility of the time windows for therapeutic intervention with those used in animal testing. The timing of intervention appears to be critically important; NMDA receptor antagonists are protective in the acute stages of injury, but interfere with the beneficial effects of NMDA receptor activation that occur after injury during recovery and repair processes (Lo, 2008b).

Other drugs such as cannabinoid CB1 receptor agonists have been tested as neuroprotectants, with mixed results. Although CB1 receptors expressed on glutamatergic neurons can play a protective role by inhibiting glutamate release, CB1 can also be expressed on GABAergic neurons, and have an excitatory effect by inhibiting GABA release. As a result, cannabinoid CB1 agonists have given mixed results for neuroprotection, with no drugs in development. Similarly, CB1 receptor antagonists are protective in some models, but translation to the clinic does not seem likely at the time of writing (Ashton and Glass, 2008).

Despite the narrow time window for beneficial results from the administration of glutamate receptor antagonists and the problems with delayed administration of NMDA receptor antagonists, other glutamate receptors may still be a target for pharmacological management of hypoxic encephalopathy. Neonatal hypoxia is associated with seizures, which may either be a cause or a consequence of encephalopathy. This has suggested suppression of neuronal excitation as a treatment to reduce the long term effects of neonatal hypoxia. There are many possible targets for intervention, including most of the traditional targets for anticonvulsant and antiepileptic therapy, including glutamate receptors, GABA receptors and voltage sensitive sodium channels. Rat studies have indicated that inhibition of excitatory amino acid neurotransmission may be better in this respect than agonists at inhibitory receptors, such as benzodiazapenes (Jensen, 1995).

Talampanel (GYKI53773) is a non-competitive AMPA receptor antagonist (Aujla, Fetell, and Jensen, 2009) which has been shown to reduce seizures in a dose-dependent manner in a rat model of neonatal hypoxia. Given that seizures are predictive of brain damage in hypoxia ischemia (Jack R. Rivers, et al., 2011) then talampanel could mark a change in strategy for the pharmacological management of CNS excitation in neonatal hypoxia, shifting from neuroprotection in the acute phase to the reduction of seizure-induced injury in the delayed phase of damage. Talampanel is under trial as antiepileptic drug in children and so may be used in the near future in the treatment of seizures associated with neonatal hypoxic encephalopathy. There is also some evidence of neonatal seizures can be successfully treated with traditional CNS depressants such as short acting benzodiazapenes (Sirsi, Nangia, LaMothe, Kosofsky, and Solomon, 2008). As there is considerable overlap between management of epilepsy subsequent to hypoxic encephalopathy and the reduction of seizure induced brain damage, then despite their failure as neuroprotectants in the acute phase of injury CNS inhibitors are likely to play a significant role in the pharmacological management of hypoxia ischemia.

5.2.1.2. Antioxidants

Drugs that target oxidative stress by ROS or RNS, antioxidants, like NMDA receptor antagonists, provide significant neuroprotection in animal models (Clarkson, et al., 2004; Gitto, Pellegrino, Gitto, Barberi, and Reiter, 2009; Sutherland, et al., 2004). However, also

like NMDA receptor antagonists, these drugs have failed to work in the clinic. To take one well discussed example, NXY-059 is a free radical spin trap that unexpectedly failed in clinical trial in the SAINT-2 trial (Shuaib, et al., 2007).

Aside from the issue of the applicability of animal models to humans, there are at least three major arguments for why anti-oxidants have failed in clinical trial. First, cells contain a battery of endogeneous antioxidant mechanisms, such that oxidative stress is the result of an imbalance between free radical and ROS production and endogenous protective mechanisms. Therefore, the concentration of exogenous antioxidants to the sites of injury has to provide at least as much protection as that provided by endogenous mechanisms to be of benefit. The delivery of antioxidant drugs to potential sites of action has been challenging, and has been the topic of a great deal of innovative and ingenious research. Despite this, there is a large experimental gap between the behaviour of antioxidants *in vitro* and their effects *in vivo*.

However, this does not explain why antioxidants have been successfully used in animal models, and so some researchers have argued that exogenous antioxidants do reach key sites of action in significant quantities, but have complex effects depending upon subtleties of timing, dose, and physiology. Reactive oxygen and nitrogen species are not only causes of damage at high concentrations, but are also signaling molecules in various aspects of physiology and homeostasis; for example, the maintenance of blood-flow. Moreover, sustained antioxidant treatment might cause adaptive changes in endogenous protective mechanisms, with unpredictable effects. And in a similar way to NMDA antagonists, although blockade of oxidative stress may be protective in a short time window of acute injury, antioxidants may have biphasic effects such that delayed administration interferes with essential recovery and repair processes (Lo, 2008b).

A third argument maintains that antioxidant therapy may well remain a viable treatment strategy for neuroprotection, but preclinical research has been of insufficient quality to support the decisions that have been made to move drugs into clinical trial. Macleod et al. (Macleod, et al., 2008) have argued persuasively that the pre-clinical evidence for NXY-059 did not warrant progress to clinical trial, and that close analysis of the preclinical studies reveals a paucity of evidence for the drug's efficacy, with effects overestimated due to a lack of rigor in experimental design. The authors argue that this could be corrected by the widespread adoption of publication standards for preclinical animal studies similar to those that are now standard for clinical trials.

5.2.1.3. Anti-Inflammatory Drugs

If it is true that putative neuroprotectants necessarily have biphasic or even multiphasic effects dependent upon timing of delivery with respect to the phase of injury and recovery (Lo, 2008b), then this applies equally to anti-inflammatories. But unlike NMDA receptor antagonists and antioxidants, anti-inflammatories tend to have beneficial actions in the delayed phase of injury, whereas delivery at the acute phase can interfere with vital triggers to endogenous protective and recovery mechanisms.

The two most commonly used classes of anti-inflammatory drugs are corticosteroids and non-steroidal anti-inflammatory drugs (NSAIDs). Neither of these has proven suitable for treatment of cerebral ischemic injury. NSAIDs have strong effects on haemostasis; traditional NSAIDs increase risk of hemorrhage, and selective COX-2 inhibitors increase the risk of thrombosis. It is not clear as yet whether these limitations will apply to all drugs that target the arachidonic acid pathways such as leukotriene inhibitors. With respect to steroids, not

only is there no evidence for any beneficial effect the acute phase of injury (De Reuck, et al., 1988; Norris and Hachinski, 1986) but various lines of evidence suggest that high dose steroid treatment can cause microvascular injury and vasospasm (De Reuck, et al., 1988; Edlow, et al., 2010; Linn, Desilva, and Peeters-Asdourian, 2009). Because of this, testing of non-traditional anti-inflammatory drugs in animal models of cerebral ischemia is an active field of research. For example, minocycline is neuroprotective in a range of models, including hypoxia ischemia (Cai, Lin, Fan, Pang, and Rhodes, 2006; Familian, Boshuizen, Eikelenboom, and Veerhuis, 2006; Maier, et al., 2007).

Another example of a non-traditional anti-inflammatory target is the cannabinoid CB2 receptor (J. R. Rivers and Ashton, 2010b). Agonists for the CB2 receptor have been shown to be potentially neuroprotective in cerebral ischemia (Zhang, et al., 2007) although it has not yet been determined whether this is due to an anti-inflammatory effect, and whether CB2 activation is neuroprotective in the secondary phase of cerebral ischemic injury.

5.2.2. Rehabilitation and Repair

Just as non-pharmacological interventions have focused both on limiting brain damage during injury and on enhancing recovery of function through rehabilitation programs, so pharmacological strategies include not only neuroprotective drugs but also drugs that may act in a way to facilitate the plasticity of neural and associated tissue that is central to repair and recovery.

5.2.2.1. Neural Plasticity

The emerging evidence that drugs that are neuroprotective in the acute phase of injury can be damaging in the secondary phase (and vice versa) highlights the importance of the recovery and repair processes that take place after acute injury. The secondary phase of injury involves not only ongoing cell death, but also changes in microvasculature due to angiogenesis, neuronal remodeling such as that due to axonal sprouting, complex patterns of neuronal arrest and recovery due to endogenous inhibitory mechanisms, and more controversially, the generation of new cell cells from neural progenitors. A highly orchestrated and complex inter-related series of events takes place in the hours, days and months following cerebral injury, and only recently has it become clear that processes that are damaging over the short term in one phase of injury may provide vital triggers for recovery processes that follow (Lo, 2008b). To give three examples: (i.) matrix metalloproteinase (MMP) inhibitors are protective in the acute phase of injury by stabilizing the microvasculature, but are vital for vascular remodeling and angiogenesis in the recovery phase (S. R. Lee, et al., 2006); (ii.) activated microglia and macrophages may be cytotoxic in one phase of injury, but through phagocytosis perform a vital role in preparing tissue for subsequent axonal sprouting and remodeling; (iii.) although over-activation of NMDA-receptors leads to excitotoxicity in the acute phase of injury (above), functioning NMDA receptors appear to be vital for not only the activation of endogenous neuronal protective mechanisms (Papadia, Stevenson, Hardingham, Bading, and Hardingham, 2005) but are also a central element in the regulation of the synaptic plasticity that is critical for the remodeling of neural networks in the recovery phase.

Considerations about the timing of delivery of protective drugs aside, pharmacological strategies for enhanced neural plasticity are still in the conceptual stage. Identification of biochemical targets for increased plasticity is a goal, but to our knowledge not yet an

established reality. Neurotrophic factors, neurosteroids, and glutamate receptor modulators are just some examples. However, one promising approach has been suggested by recent research by Clarkson et al. (Clarkson, Huang, Macisaac, Mody, and Carmichael, 2010) who used an inhibitor of GABA transport to enhance motor function in mice following stroke. GABA transporter dysfunction is thought to be a contributing element to the tonic inhibition of neural activity in the penumbral regions of cerebral injury, such that substantial neural capacity may not be truly lost, but be simply in a state of arrest. Disinhibition of these arrested neurons in the delayed phase of injury may not only provide some immediate recovery of function, but by restoring normal neural activity allow for ongoing neural plasticity. An optimal strategy for the use of such drugs would seem to be as adjuvant to physical therapy, with drug treatment allowing for the neural activity necessary for the plastic changes guided by a rehabilitation program. Ideally, drugs will be found to enhance neural plasticity such that the effects of physical rehabilitation may be even further accelerated and amplified.

5.2.2.2. Neurogenesis

Since the discovery that there are two areas of the brain that produce new neurons throughout adult life (the sub-granular layer in the hippocampus and the sub-ventricular layer in the striatum) there has been hope that this may be exploited to improve recovery from injury (Okano and Sawamoto, 2008). However, although it seems clear that neurogenesis contributes to neural plasticity in the hippocampus and the olfactory bulb in healthy adults, it has not yet been determined whether the production of new neurons in the pathological brain is part of a recovery process (Vert and Daval, 2006). Neurogenesis is upregulated in a variety of neural pathologies, including chronic neurodegenerative diseases such as Huntington's disease (Vazey and Connor, 2010) and following acute injury such as stroke (Kozorovitskiy and Gould, 2003). Whether this is part of an endogenous repair process or merely an epiphenomenon of disorganized cell division, remains to be determined (Minger, et al., 2007; Zhao, Deng, and Gage, 2008).

Cells produced at the sub-ventricular layer do migrate to sites of injury following cerebral ischemia, but it has been estimated that only a small percentage of these differentiate into neurons (Vazey and Connor, 2010). Of the new neurons produced, it is not known whether they integrate into functioning neural networks and thus contribute to recovery. Following asphyxia in rats, cell proliferation is increased in the hippocampus, but most of these cells are glia (Keilhoff, John, Langnaese, Schweizer, and Ebmeyer, 2010). Therefore, instead of using one or more of the numerous drugs that are known to increase neurogenesis (Jagasia, Song, Gage, and Lie, 2006), a more nuanced treatment strategy would be to alter the microenvironment of the injured regions of the brain in such a way that facilitates cell survival, differentiation, and integration. Due to the potential impact this could have in providing more extensive neural networks for adaptive recovery, this is another field of intense research activity. By contrast, although pharmacologically tractable, it is not yet known whether increasing the rate of cell division and migration from the neurogenic zones of the brain could be hazardous. For example, it is not known whether neurogenesis is an adaptive response to epilepsy, or whether it is a causal factor (Bernardino, Ferreira, Cristovao, Sales, and Malva, 2005). A challenge for neurogenesis research in hypoxia ischemia therefore is the identification of targets for improvements in adaptive and not maladaptive plasticity.

CONCLUSIONS

Hypoxia ischemia of the neonate is a common problem that reduces quality of life and can be fatal. HI causes a range of symptoms that include cognitive impairment and motor dysfunction, which can be debilitating for a lifetime. Following the period of low oxygen and low nutrients, regular cellular processes are impaired resulting in an excitotoxic and ROS/RNS cascade that is highly toxic to both neurons and oligodendrocytes progenitor cells. Subsequent damage is followed by a long period of neuroinflammation that lasts for weeks and evens months after the initial insults and causes further damage through cytokine signaling as well as excitotoxicity and RNS/ROS compounds. Despite increasing knowledge of the details of these processes, no pharmacological interventions are currently in clinical use, and hypothermia is currently the only intervention used to prevent brain damage. A variety of animal models have been developed to study this pathology but treatments found to be efficacious in these models have not translated into the clinic. This suggests that a change in the way animal models are used is needed. When putative treatments are tested, several different species and both sexes should be used, the treatment should be administered at a clinically relevant time after neurological insult, animals should be assessed over a prolonged period of time including behavioral tests, and co-morbidities should be addressed. The latter include preterm birth, hypocapnia, hypoglycemia and, possibly, maternal infections. These shifts may already be happening, and treatments may yet emerge from existing knowledge of mechanisms of neuroprotection. Strategies that should not yet be dismissed include anti-inflammatory treatment, inhibition of CNS excitation, antioxidant therapy, and facilitated neuroplasticity. The challenge now for researchers is to determine optimal times, doses, and regimes for maximizing the potential benefits of these treatments whilst minimizing the risks.

Chapter 42

SWALLOW SCREENING AS AN ESSENTIAL COMPONENT OF ACUTE STROKE MANAGEMENT

Julie Luker and Kylie Wall

ABSTRACT

Dysphagia following stroke is common and increases patient risk of poor outcomes and adverse events. Swallow screening is an important process of care for patients who suffer acute stroke. This brief examination aims to identify those patients that may be at risk of swallowing problems so that comprehensive assessment and management can be provided. However, despite wide agreement that swallow screening is an essential component of care, there is no agreement regarding how or when screening should be performed, and by whom. Debate continues regarding the validity and reliability of various screening tools, and whether they are able to provide an acceptable level of certainty in risk detection. Our chapter reviews the current evidence underpinning swallow screening for acute stroke patients.

Published clinical quality audits on acute stroke populations have reported suboptimal compliance with swallow screening. Current evidence suggests that multiple factors contribute to screening compliance, including the structures and systems within health care facilities, such as stroke unit care. The provision of swallow screening may also be influenced by demographic and stroke-related variables of the patients themselves, such age, gender and stroke severity.

The results of the authors' recent research on the factors that influence the quality of stroke swallow screening will be presented. This was conducted in three Australian tertiary hospitals. The study retrospectively audited the care provided to 300 patients admitted with acute stroke. Data was collected on swallow screen compliance and other variables of interest including stroke unit admission, day of admission, patients' age, gender, English proficiency, comorbidities, pre-stroke levels of independence and type of accommodation, stroke severity and length of stay. Logistical univariate and multivariate stepwise regression analysis was undertaken to explore the determinants of screening compliance in this population. In the sample, patients with milder stroke, and those admitted over a weekend, were at increased risk of not receiving a swallow screen.

Swallow screening is an accepted care process in acute stroke management, despite ongoing debate regarding the best way to conduct the screening. Studies, including our own, report suboptimal provision of swallow screening. The factors that influence

swallow screening compliance may be complex and include variables within hospital systems, as well as variables related to the patient and their stroke.

INTRODUCTION

Stroke is a major health issue internationally. In Australia alone around 60,000 people suffer stroke annually making it the country's second greatest cause of death and the leading cause of disability (1, 2). The past decade has seen an increase in research evidence regarding the best care for acute stroke patients, aimed at optimising their outcomes. This has led to the development of high quality stroke guidelines to steer clinical care (3). Guideline recommendations encompass the prevention of complications associated with stroke-related mortality and other poor outcomes (4).

Oropharyngeal dysphagia is a common consequence of stroke and it increases patient risk of post-stroke complications. Reported incidence of dysphagia varies, with an Australian national audit reporting 47% (5), and instrumental videofluoroscopic examination reporting that dysphagia affects 64 – 78% of stroke patients (6). About half of these patients with dysphagia will recover a functional swallow within a week, but the remainder may experience dysphagia for several months or longer (6, 7). A systematic review and meta-analysis conducted by Martino's group (6) confirmed that patients presenting with dysphagia had a significantly increased risk of developing pneumonia (RR 3.17; 95% CI 3.3-39.7). Dysphagia is also associated with increased risk of malnutrition and dehydration, increased length of stay and in-hospital death (6, 8, 9). Given the serious potential consequences of dysphagia, it is unsurprising that the detection, assessment and management of this condition is prominent in stroke guidelines.

The provision of routine swallow screening had been shown to improve patient outcomes and reduce the occurrence of pneumonia following acute stroke (10, 11). However, despite wide agreement that swallow screening is an essential component of care, there is no agreement regarding how or when screening should be performed, and by whom.

In this chapter, swallow screening is defined as a brief examination of swallow function which aims to detect patients who may be at risk of swallowing problems so that comprehensive assessment and management can be provided. Patients found to have a safe swallow at screening, can commence oral intake without the delay of waiting for a specialist assessment (12). Screening is often administered by non-specialists in dysphagia including nursing staff, or any other member of the multi-disciplinary team. Ideally, screening requires minimal training to educate the screening staff on the basic understanding of dysphagia and administration of the screening tool.

In this chapter screening is differentiated from a comprehensive bedside swallow assessment, which is defined as a more detailed procedure performed by clinicians with specialised knowledge in dysphagia and skills in interpreting findings, such as a speech pathologist.

WHEN TO SCREEN AND BY WHOM?

We recently conducted a systematic review on the use of process indicators to determine the quality of care provided to patients with dysphagia following acute stroke (13). All 21 reviewed articles used process indicators for swallow screening as a measure of quality stroke care. However there was no agreement regarding the optimal timing of screening: seven articles specified screening performed before oral intake, seven used a timeframe of within 24 hours of admission, while seven authors did not mention timing as a quality-of-care consideration. As most of the reviewed articles were retrospective studies, it is possible that this equivocal evidence on the best time to screen reflected pragmatic difficulties of collecting retrospective data on oral intake, rather than sound evidence of effectiveness. *A priori* reasoning would suggest that oral intake should be forestalled until a safe swallow is confirmed, and this is in fact reflected in recent clinical guideline recommendations (3)(p82).

There are no current evidence-based recommendations for the level of training required to perform a swallow screen. Australia's Clinical Guidelines for Stroke Management simply specify that "Personnel specifically trained in swallow screening using a validated tool should undertake screening" (3)(p82). Speech Pathologists or Speech & Language Therapists (SPs) are recognised experts in the assessment and management of dysphagia (14). However, given the requirement for rapid swallow screening for all stroke admissions over seven days a week, allocating this role to SPs is an inefficient use of resources (12). Emerging evidence suggests that training nursing staff to conduct swallow screening is a feasible option. Cichero's study (12) with stroke and non-stroke patients reported that nurses who undertook a detailed training program conducted by SPs were able to adequately detect the risk of dysphagia on screening. Compared to repeated screening conducted by SPs, nurse-screening had 95% sensitivity and 97% specificity. This is supported by the Weinhardt et al. (15) study, where 94% agreement was demonstrated in swallow screen results when conducted by registered nurses and SP staff with a population of acute stroke patients.

SCREENING TOOLS AVAILABLE

Debate continues regarding the validity and reliability of various screening tools and whether they are able to provide an acceptable level of certainty in dysphagia detection. Current stroke clinical guidelines have been unable to make many specific recommendations due to a lack of clarity in the underpinning evidence (3, 6). A large number of studies have attempted to establish the most valuable screening tools, however flawed methodological quality and variability between studies has failed to lead to a unanimous conclusion (6, 10).

The accuracy of swallow screening in detecting stroke related dysphagia is particularly difficult for the proportion of patients who exhibit no overt signs of aspiration, such as coughing. This silent aspiration has been reported in 28-52% of acute stroke patients (16). The Nakajoh et al. (2000) study on stroke patients revealed that the latency of the cough reflex was significantly associated with the incidence of pneumonia (17). Therefore screening tools that depend on an overt cough response to penetration and/or aspiration may miss many stroke patients who are at risk.

Variable information is available on the psychometric properties of some swallow screening tools. Determining validity, sensitivity and specificity relies on the ability to compare findings from screening tools to a recognised ‘gold standard’ however agreement on a reference standard for detecting post-stroke aspiration has been problematic (18). While videofluoroscopy (VFS) has been long considered the reference standard for swallow assessment (19), this is not unanimously accepted for acute stroke patients (18). Problems exist with the feasibility of using VFS following stroke, especially for severely affected patients with poor sitting balance. Furthermore, the inter-rater reliability data on VFS to detect dysphagia is also poor (20, 21), and evidence is still emerging regarding the best materials and measurement tools to use during testing (22, 23) .. Fiberoptic endoscopic evaluation of swallow (FEES) is an alternative reference standard for swallowing screening, and FEES has demonstrated sensitivity and specificity values which are comparable to VFS. Although it is an invasive procedure, FEES may be more feasible for use in acute stroke due to bedside portability and reduced radiation exposure (24). Whether using FEES or VFS as the reference test, recent validation studies use penetration to the level of vocal folds and/or aspiration as the end point of testing (25).

Intermittent systematic reviews have tracked the availability of new swallow screening tools over time (18, 25-27). The following is a summary of screening tools which are freely available. Tools were only included where data were available from stroke population studies, and where validity was assessed against the reference tests of FEES or VFS.

Recommended swallow screens that met these criteria were:

- 50ml (3oz) or 90ml (3oz) Water Swallow Test (28-31),
- Gugging Swallow Screen (GUSS) (32)

Table 1 details the psychometric information available for these screening tools. The sensitivity measures indicate the ability of the tool to detect ‘risk’ when it is present, while specificity indicates the tool’s ability to produce negative results for patients who are not ‘at risk’ (27).

A simple pulse oximetry test, in conjunction with 50ml Water Swallow Test, is reported to increase sensitivity and specificity (28, 30) as detailed in Table 2.

The swallow assessment or screening tools which were excluded from our recommendations are detailed in Table 3. The majority of exclusions (seven tools) were due to insufficient validation of the tool, four were considered to require expert interpretation of findings and were therefore unsuitable for inter-disciplinary screening, and one tool was not freely available. Despite these short comings, this information provides a comprehensive over-view of published resources.

SWALLOW SCREENING FOR ALL?

Current stroke clinical guidelines recommend swallow screening or assessment for all patients with acute stroke. The authors' recent systematic review reported on 25 studies which examined the quality of care provided for patients with dysphagia in acute stroke settings (13). The majority of these studies (21) included swallow screening as a process indicator of quality. Studies frequently reported poor compliance with the administration of swallow screening, which varied between settings for unclear reasons. To illustrate, Reeves et al. (2008) (43) reported that only 55.6% of patients across 857 United States hospitals with an acute stroke had received a screen. By comparison the national audit of 96 Australian hospitals reported that 64% of patients were screened within 24 hours of admission (5). Rudd et al. (2007) (44) described differing compliance across 46 United Kingdom hospitals depending on access to stroke unit care (73% compliance) or no stroke unit (66% compliance).

Minimal investigations have been undertaken to explore the reasons why some patients receive evidence-based care such as swallow screening, while others do not. Current evidence suggests that multiple factors contribute to the provision of quality care, including the structures and systems within health care facilities, such as stroke unit care (44, 45). However the provision of swallow screening may also be influenced by demographic and stroke-related variables of the patients themselves, such age, gender and stroke severity. Before quality improvement activities can target barriers to care, a better understanding is needed of which patients are at risk of suboptimal care.

A STUDY OF SWALLOW SCREENING COMPLIANCE

A recent study by the authors explored the determinants of quality care for acute stroke patients (46, 47). One of the indicators of quality care in this study was that patients received a swallow screen within 24 hours of admission to hospital.

Methodology

Ethical approval was gained to conduct a retrospective clinical audit of consecutively sampled acute stroke patients' medical records.

Sample Size

Three hundred medical records were sampled, 100 each from three large metropolitan tertiary hospitals in Adelaide, South Australia, Australia. This sample size was sufficiently powered at $\alpha=0.05$, $\beta=0.8$ for sub-group analysis.

Inclusion and Exclusion Criteria

Patients' medical records were included if they had been consecutively admitted prior to August 31st 2009 with an IDC10 diagnostic code of acute stroke which was confirmed by diagnostic imaging or clinical evidence.

Quality of Care Measures

In an earlier systematic review we determined that *swallow screening performed within 24 hours of admission* was one appropriate measure of quality of care provided in acute stroke settings (13). Compliance with this process indicator became the dependent variable for our investigation into the factors which influence care quality for patients with stroke related dysphagia.

Data

Data were extracted from patient records on the independent predictor variables of patients' age, gender, pre-morbid levels of independence and accommodation type, English proficiency, comorbidity levels (Charlson Comorbidity Index), weekend or weekday admission, stroke unit admission, initial stroke severity (NIH Stroke Scale), length of stay in the acute hospital (LOS), and process indicator compliance. De-identified data from all patient records were manually extracted and entered onto a purpose built MS Excel spreadsheet.

Data Analysis

We undertook a series of analyses using univariate logistic regression models to understand the relationships between the predictor variables and compliance with swallow screening. Details of this analysis, and the way that data were managed, are available elsewhere (46, 47). Correlations between variables were expressed as odds ratios (OR) and 95% confidence intervals (95% CI).

Results

Description of Participants

The mean age of the 300 sampled patients at hospital admission was 74.7 years (Standard Deviation (SD) 13.5, range 18–100 years). The sample was proportionally balanced for gender. The mean (SD) ages for males and females were similar, however a larger proportion of females were in the older age groups with 72% females aged 75 years or older, compared to 53% males. A greater proportion of females suffered a moderate or severe stroke (28%) than males (18%). For the whole sample, there were weak relationships between increasing age and higher comorbidity levels ($r^2 = 0.20$), and increasing stroke severity ($r^2 = 0.21$). The mean length of stay in acute care was 12.5 days (SD 15.6, range 1–98 days).

Process Indicator Compliance

Compliance with the process indicator was poor, with only 51.6% of eligible patients receiving a swallow screen within 24hrs of admission.

Variables associated with Swallow Screening Compliance

Univariate logistic regression modelling determined that three of the 10 predictor variables were significantly associated with swallow screening compliance (see Table 4).

Table 4. Univariate model of independent predictor variables and swallow screening.

Predictor variables	Screening compliance
Age (75+ yrs)	1.02 (0.63 – 1.66)
Gender (female)	0.75 (0.47 – 1.21)
Mild stroke severity (NIHSS $\leq$ 8)	0.37 (0.23 – 0.61)**
High comorbidity (CCI $\geq$ 1)	1.29 (0.77 – 2.15)
Previous Independence	0.90 (0.54 – 1.49)
Previous residential care	1.52 (0.73 – 3.17)
Stroke unit admission	0.99 (0.62 – 1.60)
Weekend admission	3.09 (1.84 – 5.22)**
Length of stay (<12 days)	0.50 (0.30 – 0.82)**
English proficient	1.31 (0.54 – 3.13)
Odds Ratios (95% CIs) ** significant	

Patients with a mild stroke (NIHSS $\leq$ 8) or a shorter LOS (< 12days) were less likely to be screened than patients with more severe strokes, or those with shorter hospital stays. Swallow screens were significantly more likely to occur for patients admitted on a weekday compared to weekend admissions.

Accounting for Confounders

Additional univariate analysis demonstrated complex and potentially confounding statistical relationships between several predictor variables (47). This is depicted in Figure 1.

Figure 1. Potentially confounding relationships between predictor variables.

Logistical stepwise multivariate models were used to account for confounders. Only two variables were significantly associated with the provision of swallow screening, after confounders were considered in analysis (Table 5).

Table 5. Variables associated with swallow screening after accounting for confounders.

Predictor variables	Screening compliance	
	Chi ² [Freedom°]	OR (95% CI)
Mild stroke severity (NIHSS≤8)	16.2 [1]	0.4 (0.2-0.6)**
Length of stay (<12 days)	19.0 [2]	0.6 (0.4-1.1)
Weekend admission	36.1 [2]	3.3 (1.9-5.7)**

** statistically significant finding OR= Odds ratio
95%CI= 95% Confidence Interval

Discussion of Study Findings

This study provides new findings regarding the factors which may relate to compliance with swallow screening for acute stroke patients. Our findings support earlier studies reporting the sub-optimal use of swallow screening in practice. The complex associations identified between independent variables indicate that there are unlikely to be simple explanations for why some patients receive recommended dysphagia care and others do not.

We acknowledge that the generalizability of the findings may be limited by some variables chosen in our study, due to international variations in health care policy and systems. Length of stay data and admissions directly to a stroke unit, for example, are both particularly influenced by local contexts.

Our results indicate that patients admitted over a weekend or with mild strokes (NIHSS scores ≤8) may be at particular risk of missing swallow screening. Previous studies have also reported poor quality care for patients admitted over weekends, and have linked this to worse outcomes for these patients (44, 48). The reasons for day-dependent differences in care standards are unclear but are likely to be associated with the reduced availability of trained staff and different operational systems over weekends. It appears that staff are mindful of performing a swallow screen for patients admitted with a severe stroke, perhaps due to more visible cues of risk. However there is no evidence that patients with milder strokes (as determined by NIHSS) are at less risk of dysphagia than patients who have had a more severe stroke. The recommendation of swallow screening for all stroke admissions needs to be more universally implemented.

IMPROVING COMPLIANCE WITH SWALLOW SCREENING

The principles of translating evidence into clinical practice have been well documented by implementation scientists in recent years (49-51). Strategies specific to clinical management in acute stroke settings are emerging and could be applied to the improvement of effective swallow screen processes (11, 12, 52-55). Evidence based strategies that could be considered include: organisational assessment of readiness for practice change, identification of barriers to change, effective involvement of key stakeholders, development of incentives to

change, targeted education programs, and the guided roll-out of the new practices followed by cycles of clinical auditing and feedback.

The research outlined above suggests that there are particular sub-groups of acute stroke patients who may be at increased risk of poor dysphagia management. The swallow screening implementation strategies should ensure that these at-risk groups are carefully considered.

CONCLUSION

Dysphagia is a common consequence of stroke that must be identified early after onset and managed carefully to avoid negative outcomes. Swallow screening for all acute stroke patients is recommended best-practice to efficiently detect those patients at risk of swallowing problems. Debate continues regarding the best way to conduct screening, and screening alone is unlikely to detect silent aspiration. This chapter identified two swallow screening tools that have proven sensitivity and specificity in the acute stroke population. Both these tools can be used by staff from various disciplines, after minimal training. The effective application of swallow screening within clinical settings is challenging. Current evidence suggests that universal swallow screening is not well translated into clinical practice. Some patients may be at greater risk from unidentified dysphagia than others. The results of our recent study demonstrated that patients admitted over a weekend and those with milder strokes were more likely to miss out on timely swallow screening. Acute stroke facilities should consider systematic ways to ensure optimal care for all patients.

ABSTRACT

Background: Cerebral blood flow (CBF) in chronic stage after cerebral stroke is considered to reflect a brain function. All the brain structures mutually influence, however, various territories show specific functions. We investigated territories that strongly affected activities of daily living (ADL) by using Xenon-enhanced computed tomography (Xenon CT).

Methods: A total of 130 patients with an average age of 67 years, including 80 patients with unilateral cerebral hemorrhage and 50 patients with unilateral cerebral infarction, were enrolled in this study. Xenon CT was performed 39 days on average after stroke onset to predict rehabilitation outcomes, and the ADL was evaluated using the functional independence measure (FIM) at hospital discharge, 104 days on average after stroke onset.

Results: 1. In all groups of right/left cerebral infarction and hemorrhage, mean CBF (mCBF) values on average of the lesion side were from 24.7 ml/100g/min to 27.9 ml/100g/min, and significantly decreased with differences of 6.1 ml/100g/min to 3.3 ml/100g/min in comparison with the non-lesion side. 2. Spearman's rank correlation analysis revealed that the FIM total score of right cerebral infarction was significantly correlated to both right ($r_s=0.508$, $p<0.001$) and left ($r_s=0.465$, $p<0.002$) mCBF values, however, that of left cerebral infarction was not correlated to them. 3. According to the subgroup analysis of territories about cortical and perforating arteries, only the group of right cerebral infarction with lesions in cortical artery territories showed significant correlation coefficients between FIM total scores and both right ($r=0.656$, $p<0.001$) and left ($r=0.751$, $p<0.001$) mCBF values. 4. As a common result of right and left cerebral infarction groups, regional CBF (rCBF) values of right frontal cortex and rCBF values of

right thalamus were significantly correlated to FIM motor scores, and rCBF values of right and left putamen were significantly correlated to FIM cognitive scores. 5. Cerebral hemorrhage did not show the same results as cerebral infarction, supposedly due to mass effect of hematoma.

Conclusion: Our results seemed to support the idea that the function of right brain, which plays an important role in spatial recognition, influences better outcomes more than the left-brain. In addition, we proved that the putamen, which controls a various kinds of motor skills, was related to cognitive function.

INTRODUCTION

Depending on brain activities such as motor and cognitive functions, normal brain tissue consumes oxygen and glucose, coupling with cerebral blood flow (CBF), and consequently, the CBF could be an indicator to evaluate brain focal function. However, when a cerebral stroke happens, the CBF begins to alter and shows a discrepancy between clinical symptoms and its value, such as luxury perfusion, which condition is that CBF exceeds the metabolic requirements, and misery perfusion, which condition is that CBF is lacking. During neural stimulation such as somatosensory and visual ones, imbalance of blood flow and oxygen metabolism was also observed [1]. Accordingly, the CBF in acute stage after stroke onset is inappropriate to be a parameter to evaluate the brain function. Nevertheless, in the chronic stage of cerebral stroke, the CBF resumes to agree with both cerebral circulation and functions, and hence the CBF at rest in the chronic stage comes to be a scale to assess the brain function.

There are a variety of modalities to evaluate the CBF and related metabolic values such as positron emission computed tomography (PET), single photon emission computed tomography (SPECT), functional magnetic resonance imaging (MRI) [1], and near infrared spectroscopic topography (NIRS) [2]. Xenon-enhanced computed tomography (Xenon CT) [3], which provides quantitative regional CBF (rCBF) values with a CT scan and a simpler system, is also a useful method to assess the brain activity.

We reported that the CBF in the chronic stage had a significant relation with the activities of daily living (ADL) at the end of stroke rehabilitation using Xenon CT [4]. In the study, we concluded that right mean CBF (mCBF) tended to be more closely correlated with functional independence measure (FIM) total scores at discharge than left mCBF indifferent to the type of stroke. The FIM is a scale to evaluate ADL of patients with a stroke or other neurological disorders from both sides of motor and cognitive function. The pathological features are different among cerebral infarction (CI), intracerebral hemorrhage (ICH), subarachnoid hemorrhage (SAH), and other strokes. Moreover, the CBF and FIM are also influenced by a lot of factors such as age, gender, hematocrit, neurological deficits and contra-lateral lesions. Accordingly we focused on supra-tentorial unilateral stroke with CI and ICH to investigate the territory that strongly affected FIM.

There are apparent functional differences between the right brain and the left brain. The right hemisphere is important to space perception, and the left hemisphere is important to logical recognition including language. In this paper, we investigate the brain area, which is essential to obtain the better outcome in stroke rehabilitation, by means of the FIM and the CBF measurements.

METHOD

Subjects

One hundred ninety five first or relapsed stroke patients were admitted to our rehabilitation ward through our acute stroke unit or other acute stroke facilities during the period from March 2007 to November 2010. The medical conditions to be admitted to our rehabilitation ward were: (1) It is less than 2 months after the onset of stroke or its related surgery, (2). Effects of rehabilitation are expected in patients with hemiplegia, aphasia, ataxia, or mental disorders, etc. due to stroke. (3) There are no remarkable difficulties in staying at rehabilitation wards. (4). Patients planning to discharge to home are given priority. Comprehensive in-patient rehabilitation was given 5 days a week by our rehabilitation team, composed of 5 medical doctors, 6 physical therapists, 4 occupational therapists, 3 speech therapists, 3 social workers, and 15 rehabilitation nurses.

The inclusion criteria of this study were also the same as we reported as: (1) patients 25 days or above after onset, avoiding the acute and sub-acute stroke patients; (2) no major complications and no re-stroke during the stay in the rehabilitation ward; (3) confidence values of Xenon CT less than 1.4, which derived from an average + 2 SD (standard deviation) value obtained initial 120 cases of Xenon CT examinations; (4) hematocrit values more than 31%, which were led from the minimum value of female control [4]. In addition, we excluded the patients with SAH, infratentorial stroke and bilateral hemispheric stroke with old lesions more than 1cm in size in the non-newly affected lesion side.

Written or verbal informed consent was obtained from all patients prior to participation, and the ethics committee of our hospital approved this study.

CBF Measurement

CBF images were obtained using a Toshiba Asteion or a Toshiba Asterion multi-detector CT (MDCT) with 8 mm thickness $\times$ 4 slices and an Anzai AZ-726 stable xenon gas rebreathing system just before moving from the acute stroke unit to the rehabilitation ward. Serial 9 images were processed with AZ-7000W98 at the level of upper midbrain, thalamus, and lower and upper lateral ventricles, parallel to the orbito-meatal line. Regions of interest (ROIs) were drawn on frontal cortex, parieto-temporal cortex, occipital cortex, putamen, thalamus and whole hemispheric area at the level of thalamus for mCBF. The cortical rCBF values were averaged with upper 3 slices as shown in our previous report. To reduce motion artifacts, patients were secured with a vacuum lock head holder and earplugs we designed [4].

Functional Independence Measure

Functional outcome was assessed using FIM, which contains 13 subcategories of motor function and 5 subcategories of cognitive function. The FIM measures self-care (6 items), sphincter control (2 items), transfers (3 items), locomotion (2 items), communication (2 items), and social cognition (3 items). Each item, where 1 represents total dependence and 7

indicates complete independence, is scored from 1 to 7 based on level of independence. Possible total scores range from 18 to 126, with higher scores indicating more independence.

Statistical Analysis

Statistical analysis of the data was performed using EXCEL for Windows. Descriptive statistics were used to present the nature of all variables collected, including age, gender (male), CBF values, hematocrit values, FIM scores at discharge, onset to Xenon CT examination interval (OXI), length of chronic rehabilitation (LOCR), which length means the duration staying in the rehabilitation ward, national institutes of health stroke scale (NIHSS) at the time of Xenon CT examination, and lesion size, which is allocated 1, 2, and 3 in cases of maximum diameter of a dominant lesion less than 2 cm, 2 - 4 cm, and more than 4 cm respectively. The categorical factor of gender (male) was dummy-coded in the analysis: a positive factor is allocated 1 and a negative factor is allocated 0. Percentages, mean values, SD, the uni-variate analysis of variance, chi-test, and the analysis of regression coefficient were calculated where appropriate. Paired samples t-test was used to determine if there were any significant differences in right and left mCBF values. Multiple linear regression analysis in a stepwise manner was used to discriminate variables affecting FIM score at discharge. Spearman and Pearson correlation coefficients were used to examine the strength of relations between CBF values and FIM scores. The level of statistical significance was set as $p < 0.05$.

RESULT

A total of 130 patients, which consisted of 80 (62%) CIs and 50 (38%) ICHs were enrolled in the study. There were 78 men (60%) and 52 women (40%). The mean (SD, range) age was 67 years (13, 24-94 years). We excluded 12 patients with SAH, 24 patients with bilateral lesions and 29 patients with posterior-fossa lesions. The OXI was 38 days (10, 22-86 days) in total, 39 days (10, 22-57 days) in the CI group, and 38 days (11, 24-86 days) in the ICH group. Demographic and clinical characteristics of the patients were listed in Table 1.

Absolute average mCBF values of right and left were 25.1 and 28.4 ml/100g/min in the right CI group ($n=46$), 29.8 and 26.0 ml/100g/min in the left CI group ($n=34$), 24.7 and 30.7 ml/100g/min in the right ICH group ($n=29$), 33.0 and 27.9 ml /100g/min in the left ICH group ($n=21$), respectively. Mean CBF values on average of the lesion side decreased significantly with differences of 3.3 ml/100g/min in the right CI group, 3.8 ml/100g/min in the left CI group, 6.1 ml/100g/min in the right ICH group, and 5.1 ml /100g/min in the left ICH group, in comparison with the non-lesion side.

There were significant correlations of mCBF values between lesion sides (y) and non-lesion sides (x) in the right CI group ($R^2=0.560$, $y = 0.827x + 1.62$), the left CI group ($R^2=0.420$, $y = 0.853x + 0.569$), the right ICH group ($R^2=0.595$, $y = 0.783x + 0.618$), and the left ICH group ($R^2=0.724$, $y = 0.725x + 3.96$). The analysis of regression coefficient showed that there were no significant differences among 4 groups, which analysis means that the mCBF of the non-lesion side varies according to change of the mCBF of the lesion side.

LOCR: length of chronic rehabilitation, OXI: onset to Xenon CT examination interval

Figure 1 shows the relation between mCBF values in the right and left sides, and FIM total scores at discharge. The mCBF values were significantly related with the FIM total scores in each group. The white triangle shows right side lesion group, and the black round shows left side lesion group. Although the correlation coefficient of the right mCBF ($r=0.375$, $p<0.001$, $n=130$) was slightly higher than that of the left mCBF ($r=0.333$, $p<0.001$, $n=130$), there is no significant difference of the correlation coefficients between them.

Figure 1. The relation between mCBF values in the right and left sides, and FIM total scores at discharge.

Multivariate analyses were performed for the purpose of identifying the factors that influenced FIM scores at discharge. Although, the analysis was carried out for all potential predictive variables and the right and left mCBF values, correlation matrix among predictive variables revealed that moderate multi-co-linearity was observed in relations between hematocrit and gender ($r=0.496$), size and NIHSS ($r=-0.405$), and right and left mCBF values ($r=0.567$).

Consequently, the factors of hematocrit, size and left mCBF values were deleted from the analysis. Stepwise backward elimination revealed that age, gender (male), NIHSS and right mCBF were significant factors ($R=0.788$, $R^2=0.621$, $P<0.001$) for the FIM total scores (Table 2). The analysis mentioned above led a formula for predicting FIM scores at discharge: Predicted FIM total score = $149-0.87A+6.1G-2.7N+0.79C$, A: age, G: gender male=1, female=0, N: NIHSS at the time of Xenon CT examination, C: right mCBF (Table 2).

Table 2. Multiple regression analysis for the FIM total scores.

stepwise-backward elimination					
Variables	Coefficients (β)	SE	95% CI	t	P value
Intercept	149.2	11.4	126.6 - 171.7	13.08	<0.001
Age	-0.87	0.11	-1.08 - -0.65	-7.96	<0.001
Gender (male)	6.15	2.94	0.32 - 12.0	2.09	0.039

Table 3. Relationship between mCBF and total FIM in supratentorial cerebral infarction.

	right mCBF		left mCBF	
	rs	r	rs	r
right cerebral infarction	0.508	0.47	0.465	0.433
n=46	$p<0.001$	$p<0.001$	$p<0.002$	$p<0.01$
left cerebral infarction	0.18	0.302	0.251	0.344
n=34	$p=0.310$	$p=0.0826$	$p=0.153$	$p=0.0464$

Rs: Spearman's rank correlation coefficient

R: Pearson's correlation coefficient

Spearman's rank correlation analysis revealed that the FIM total score of right CI was significantly correlated to both the right ($rs=0.508$, $p<0.001$) and the left ($rs=0.465$, $p<0.002$) mCBF, however, that of left CI was not correlated to the right mCBF ($rs=0.18$, ns) nor the left mCBF ($rs=0.251$, ns). Because the FIM was treated as a quantitative variable clinically, we also performed Pearson's correlation analysis in the same groups. There were significant correlations between FIM total scores and both the right ($r=0.47$, $p<0.001$) and the left ($r=0.433$, $p<0.001$) mCBF values of the right CI group and between FIM total scores and the

left mCBF values ($r=0.344$, $p=0.0464$) of the left CI group (Table 3). The right mCBF of left CI group did not show the significance ($r=0.302$, ns).

According to the subgroup analysis of the territories about cortical and perforating arteries, only the group of right CI with lesions in cortical artery territories showed significant correlation coefficients between FIM total scores and both the right ($r=0.656$, $p<0.001$) and the left ($r=0.751$, $p<0.001$) mCBF values. Nevertheless, there were no significant relations in the all groups with lesions in perforating artery territories and in the left CI group with lesions in cortical artery territories, except a slight tendency ($r=0.536$, $p<0.059$) shown in the right mCBF of the left CI group with lesions in perforating artery territories (Table 4).

We also studied the correlation between rCBF values and FIM sub-scores in CI. The FIM motor scores were significantly correlated with the rCBF of right putamen ($r=0.428$, $p<0.05$), right thalamus ($r=0.466$, $p<0.05$), right frontal cortex ($r=0.354$, $p<0.05$), right parieto-temporal cortex ($r=0.414$, $p<0.05$) right occipital cortex ($r=0.415$, $p<0.05$), left putamen ($r=0.458$, $p<0.05$), left parieto-temporal cortex ($r=0.362$, $p<0.05$) and left occipital cortex ($r=0.437$, $p<0.05$) in the right CI group, and the rCBF of right thalamus ($r=0.379$, $p<0.05$) and right frontal cortex ($r=0.345$, $p<0.05$) in the left CI group.

Table 4. Correlation coefficients between total FIM scores and mCBF depending on the territories of cerebral infarction.

	territories	n	right mCBF		left mCBF	
			r	p	r	p
right cerebral infarction	cortical artery	23	0.656	<0.001	0.751	<0.001
	perforating artery	23	0.291	ns	0.1	ns
left cerebral infarction	cortical artery	21	0.273	ns	0.347	ns
	perforating artery	13	0.536	0.059	0.235	ns

On the other hand, FIM cognitive scores were significantly correlated with the rCBF of right putamen ($r=0.368$, $p<0.05$), right thalamus ($r=0.342$, $p<0.05$) and left putamen ($r=0.385$, $p<0.05$) in right CI group, and the rCBF of right putamen ($r=0.343$, $p<0.05$) and left putamen ($r=0.477$, $p<0.05$), left thalamus ($r=0.421$, $p<0.05$) and left frontal cortex ($r=0.520$, $p<0.05$) in the left CI group. As a common result of right and left CI groups, the rCBF values of right frontal cortex and the rCBF values of right thalamus were significantly correlated to FIM motor scores, and the rCBF values of right and left putamen were significantly correlated to FIM cognitive scores (Table 5).

As for ICH, we analyzed the relation between mCBF and FIM total scores according to location of the hematoma; however, the ICH did not show the same results as CI. There were no significant relations in the group of right putaminal hemorrhage ($n=16$, right mCBF: $r=0.260$, ns, left mCBF: $r=0.214$, ns), right thalamic hemorrhage ($n=9$, right mCBF: $r=0.625$, $P=0.072$, left mCBF: $r=0.388$, ns), left putaminal hemorrhage ($n=6$, right mCBF: $r=0.262$, ns, left mCBF: $r=0.190$, ns), and left thalamic hemorrhage ($n=11$, right mCBF: $r=0.201$, left mCBF: $r=0.230$, ns).

Table 5. Correlation coefficients between regional CBF and FIM sub-scores in cerebral infarction.

diagnosis	side	FIM	putamen	thalamus	frontal	parieto-temporal	occipital

DISCUSSION

The main result of this study was that the mCBF of CI with right hemispheric lesions showed significantly correlated to FIM scores at hospital discharge but not the CI with left hemispheric lesions and the ICH. In details we described 7 results below: 1 Mean CBF of no lesion side decreased in proportion to mCBF of lesion side. 2. FIM total scores exhibited weak but significant relations to right mCBF and left mCBF in the whole group. 3. The factors of age, gender and NIHSS also influenced the FIM total scores. 4. The FIM total scores significantly correlated to right and left mCBF in the CI with right hemispheric lesions, but not in the CI with left hemispheric lesions. 5. The common structures of both right and left CI groups, which showed significant relation between rCBF values and FIM sub-scores, were right thalamus and right frontal cortex in FIM motor scores and bilateral putamen in FIM cognitive scores. 6. The CI in the cortical artery territories showed a significant relation between right and left mCBF, and FIM total scores, however not in the perforating artery territories 7. The ICH group did not showed significant correlations between mCBF and FIM total scores.

Since the interval between the time of CBF measurements and hospital discharge were about 2 months and xenon CT was performed in resting condition, the CBF values measured do not always reflect the actual brain activity during rehabilitation exercises. We consider the CBF value as the potential ability to carry out the rehabilitation program during stay in the ward. Besides, we should understand the characteristics of ROI in CBF studies. When the CBF is indicated at a low value, there are two possibilities. One is a case with the brain area in low activity. The other is a case with the ROI including no flow area such as sulcus, cistern, ventricle, cyst and necrotic lesions. Basically some gaps in ROIs were not avoidable, even if the area damaged on structural imaging was excluded in CBF analysis. Nevertheless, the rCBF values measured in ROIs seems not to be so different from actual rCBF values, because the rCBF values adjacent to lesions were always reducing.

The FIM is an ordinal scale, and then we used both Spearman rank correlation coefficient and Pearson correlation coefficient in order to ascertain the statistical relation between FIM

scores and CBF values. It is clinically used as a quantitative scores and the increase of scores reduces nursing cares. Accordingly, the FIM score is an effective parameter to evaluate the rehabilitation outcome. As Tur BS et al. reported that significant correlations were found between Brunnstrom's motor recovery stage and FIM scores both on admission and at discharge [5], the initial FIM score on admission of rehabilitation ward might be also useful to anticipate the stroke outcome.

Diaschisis is a kind of transneural suppression, and it reduces activity in connecting brain area remote from the lesion site due to decrease of the excitatory impulse from an injured region. Many authors showed the CBF decreases in a variety of diaschisis in the acute stage [6]. In the chronic stage, as we showed, mCBF values of the non-lesion side significantly decreased according to the decrease of CBF values in the lesion side. This result therefore might be explained with a transcallosal diaschisis.

Indifferent to lesion sides in our series, there were weak but significant relations between FIM total scores and both right and left mCBF values. One of the causes is speculated that the each hemisphere has own function influencing the ADL. There is an example of the contribution of the right and left hemispheres to recovery from aphasia in SPECT study [7]. They discussed the importance of both non-dominant hemisphere and language dominant hemisphere in efficient recovery of linguistic abilities, though their study was not for ADL or for chronic stroke.

Multivariate analyses revealed that age, gender, NIHSS, and CBF values were significant factors influencing FIM total scores. In general the CBF decreases with healthy aging, however it is controversial matter. Meltzer CC et al. reported that CBF may not decline with age in healthy individuals and that failure to correct for the dilution effect of age-related cerebral atrophy may confound interpretation of previous PET studies that have shown aging reductions in physiologic measurements [8]. Average CBF values of female are higher than those of male [9]. This means that a female patient shows higher CBF values than a male patient when they had the same ADL level. The factors of aging, female and NIHSS show negative influence to the outcome and the factors of CBF increase and male lead better outcome and thereby, we need to take these factors into consideration to estimate the CBF values.

Rupright J et al. showed a strong correlation between CBF and improvement of FIM scores, especially in the right brain of ischemic stroke [10]. Goto A et al. reported that the locomotion outcome was poorer in patients with a right hemispheric CI than a left hemispheric CI for the patients with middle cerebral artery infarction [11]. Shulman GL et al. reported that right hemisphere dominance during stimulus-driven shifts of spatial attention and target detection reflected asymmetries in cortical regions in the functional MRI study [12]. We also demonstrated significant relations between FIM total scores and bilateral mCBF values in the right CI group, especially with lesions in the cortical artery. The left brain deals with verbal, logical and analytic abilities, and the right brain mainly deals with spatial recognition, which function is essential to move a body more stably. Accordingly, these results seem to explain that the right brain has more influential role in better rehabilitation outcome than the left brain.

The human brain looks symmetrical, but there are several reports, which explain asymmetry. MRI revealed the asymmetries of the human brain in the review of molecular approaches [13]. Left-right asymmetry of the hippocampal synapses in primates was also reported [14].

In the detailed analysis common to both right and left CI groups, rCBF values of right frontal cortex and right thalamus showed significant relations to FIM motor scores, and rCBF values of bilateral putamen showed significant relations to FIM cognitive scores. The FIM motor score measures physical independence and corresponds to the Barthel index, and assesses eating, grooming, bathing/showering, dressing upper body, dressing lower body and toileting as the items of self care, bladder management and bowel management as the items of sphincter control, bed/chair/wheelchair, toilet, bathtub/shower as the items of morbidity, and walking/ wheelchair and stairs as the items of locomotion. The spatial recognition is indispensable to move our bodies correctly. It is reported that the right putamen, caudate nucleus, thalamus and superior temporal gyrus form a coherent corticosubcortical anatomical network in the genesis of spatial neglect in humans [15]. Therefore, our results about the relations to FIM motor scores of the right frontal cortex and the right thalamus agreed with the idea that spatial recognition is dominant in the right hemisphere. The FIM cognitive score assesses both comprehension and expression as the items of communication, and assesses social interaction, problem resolving and memory as the items of social cognition. The result that the bilateral putamen related to the FIM cognitive score implies that both left brain, which is dominant in language, and right brain are influential to communication and social cognition.

The main function of the putamen is regarded to regulate movements, and it is closely connected with substantia nigra that employs dopamine to perform its function. Cerebral cortex, basal ganglia including putamen, and thalamus have also close connections, unilaterally and bilaterally. The sensory information of the body is transmitted to parietal cortex and other cortices through thalamic radiation. In addition, the frontal lobe is a major part of dealing with activities. Degenerative disorders, such as Parkinson's disease, cause a shortage of dopamine. There was an imaging study of Alzheimer's disease, which showed the decrease in putaminal volume correlated linearly with impaired global cognitive performance [16]. Another study showed that stroke patients with basal ganglia lesions were impaired on the rule-based task, not in the information-integration task [17]. These studies suggest that the putamen takes part in the recognition activity. On the other hand, there was a report that atrophy of the putamen in dementia with Lewy bodies is a parkinsonian feature, not correlating with dementia in the volumetric MRI study [18].

The relation between FIM and CBF in the group of ICH was different from that in the group of CI. The ICH group did not show a significant correlation between FIM total scores and mCBF values. Katrak PH et al. showed that patients with ICH achieved significantly greater gains in function than patients with CI after rehabilitation regardless of the severity of disability on admission [19]. Schepers VPM et al. also reported that the time window for recovery was more restricted for patients with ICH; an increase in ADL independence was found until 10 weeks post-stroke in patients with ICH, whereas patients with CI showed recovery until 26 weeks post-stroke [20]. We speculate that intracerebral hematoma compresses adjacent normal brain tissue and causes a decrease of CBF in the adjacent tissue until early in the chronic stage, and then, a marked reduction of hematoma volume leads the CBF recovery. Accordingly, CBF values of patients with ICH cannot always correlate with stroke outcomes after rehabilitation, whereas the metabolism of cerebral tissue of CI is more directly affected by the hypo-perfusion for a long time. In our series, the OXI of ICH group is not different from that of CI group. However, the CBF of ICH group might be related to FIM, if the CBF of ICH group was measured after the disappearance of hematoma.

The human brain has a dominant hemisphere, but little is known about the reason why right and left differences develop. Some animals can sense the Earth's magnetic field and use it as a cue for guiding movements over both long and short distances [21]. And it is considered to be a kind of spatial recognition. All the animals are influenced by environment such as gravity, rotation and magnetism of the Earth. Consequently, these natural phenomena might have influenced the development of dominant hemisphere in the human brain.

CONCLUSION

This study revealed that the right and left hemispheres influence mutually, and there is a significant relation between the CBF values and its outcome, especially in case of right brain lesion. In addition, this study implies that the putamen is related to cognitive function.

ABSTRACT

This paper investigates the rationale for integrating Motor Imagery (MI, the representation of an action without any overt execution) into the classical course of physical therapy to improve motor recovery. This therapeutic approach is based on comparable structural and functional properties shared by actual execution and MI. The main damages at the central level are cerebral stroke and spinal cord injury (SCI). Hemiplegia or hemiparesis following stroke could drastically alter the contralateral motor function. In addition, somatosensory information and language may also be affected, depending on the extent of brain damage. Conversely, cognitive functions such as memories, attention, problem solving (e.g., mental arithmetic, mental travel) or MI remain generally preserved, albeit with some exceptions we will briefly consider. Therefore, it should be possible to start therapy based on mental practice early on during the rehabilitation program. Indeed, after the acute phase, there is a period during which usual rehabilitation is difficult and harmful due to the general state of the patient. This is a good time-period for starting rehabilitation with MI. SCI affect lower limbs' motor function or even the four limbs, depending on the height of the spinal lesion. In the first case, locomotion is most often removed whereas in the second, upper limb functions, e.g., pointing, grasping and manipulating objects are more or less altered. We will review the main papers focusing on SCI, at least paraplegia with specific focus on posture and locomotion, and tetraplegia with specific focus on grasping. Then, we will provide several data related to the use of MI in the rehabilitation of motor function after

peripheral injuries of different natures, e.g., joint sprain, muscle tear or bone fracture. Finally, we will describe how MI could also be considered a reliable preventive technique for preserving postural functions and locomotion especially in a vulnerable population, the elderly. We will conclude by underlying the curative and the preventive function of MI training, while considering the importance of the practice guidelines ensuring effective MI and the thorough assessment of patients' ability to form and manipulate mental images.

INTRODUCTION: MOTOR IMAGERY AND MOTOR LEARNING

Pioneering studies provided evidenced that motor imagery (MI) training had the potential to improve motor learning efficiency, when combined with actual execution. Feltz and Landers (1983) were among the first who extensively studied how different forms of mental practice, including MI, could enhance motor skill learning and sport performance. This meta-analysis showed that performing MI was not as efficient as actual execution but provided better performance than that observed in a control (i.e., no training) condition. In their revised meta-analysis (Feltz et al., 1988), the same authors confirmed these previous results. Driskell et al. (1994) further reiterated that mental practice has a positive and significant effect on performance. Its effectiveness was nevertheless moderated by the type of task, the retention interval between practice and performance, and the length or duration of the mental practice intervention, as it is observed during actual practice. In the present paper, we focus on motor function rehabilitation, a particular domain of MI intervention. We will first briefly describe the other potential domains in which MI could operate and then give the rationale for using MI under such conditions. However, several concerns related to MI use in the context of rehabilitation will be described in details. Finally, we will present several experiments in which MI brought insightful and promising results for clinical applications. Practically, we will consider central nervous system injuries (i.e., stroke and SCI) and separate these from several examples of peripheral lesions.

RELATIONSHIPS BETWEEN MI AND ACTUAL EXECUTION

Human-being has the ability to produce an internal representation of a specific motor action without any overt motor output. It is assumed that this process could help motor learning because mental practice based on MI requires the participants to have the necessary declarative knowledge related to the different features of the motor task. According to Jackson et al. (2001), the rehearsing of the task with MI can also give access to the non-conscious processes involved in learning the skilled behavior, as with physical practice. In groups of athletes or musicians who extensively mentally rehearse specific skills, several MI types could be used. Visual clues are the main material for mental practice in activities with spatial aim (tennis or ski, for example), whereas kinesthetic information is probably more useful in sports with bodily-centered techniques. Finally, musicians could primarily use auditory MI or more simply the pace and the rhythm at which a piece of music is carried out. Another remarkable domain in which MI is now considered a useful tool is for surgical skills teaching (Hall, 2002). Imagery practice provides a mechanism for the explicit learning of

surgical skills. Surgeons could train themselves by applying a set of declarative instructions mentally, i.e., associating declarative knowledge into procedural abilities (Arora et al., 2011a). They could also process stress related to surgery using MI (Arora et al., 2011b). In this latter study, decreased stress was attested through the STAI test (State-Trait Inventory test from Spielberger et al., 1970) associated with a set of physiological measures, including mean and maximal heart rate as well as cortisol level. During MI, an increase in muscle tension has often been described (Lotze and Halsband, 2006). Activation of the muscles involved in mental action could increase up to visible movements (e.g., fingers in violin players or hand movements in skiers). Considering such associated muscle activity implies that this mental practice should no longer be called MI remains to be discussed. However, it seems obvious that internally driven images would benefit from kinesthetic information and would consequently better activate the infra-conscious processes that are associated with motor task execution (Jackson et al., 2001). According to Jeannerod (1994), the neural commands for muscular contractions are probably blocked at some level of the motor system, thus preventing to send the full command within the motor pathways and inhibiting motor execution. However, a slight electromyographic (EMG) activity has often been recorded during the imagination of movement. Jeannerod (1994) early postulated that incomplete inhibition of the motor command would provide a valid explanation to account for this muscle activity. Recent data support this hypothesis. Guillot et al. (2007) provided evidence of specific changes in EMG activity according to each type of contraction, i.e., isometric, concentric, or eccentric. Interestingly, the changes in the EMG pattern mirrored those observed during physical movement, thus supporting the hypothesis of a selective effect of MI at the level of muscular activity. For example, imagining an eccentric contraction elicited a significant weaker EMG activity than during all other conditions. This result is consistent with a first validation of the hypothesis of incomplete inhibition of the motor command.

With reference to the data that we just described, MI seems functionally close to actual movement execution. As many studies previously showed that the neural networks controlling movement and the mental representation of the same movement overlap, MI could be seen as a part of the motor system (Lotze and Halsband, 2006; Hanakawa et al., 2003; Dechent et al., 2004; Porro et al., 1996; Lacourse et al., 2005). Stephan and Frackowiak (1996) compared MI with motor preparation and motor execution using positron emission tomography and described their respective functional anatomy. They also monitored EMG, Hoffmann's-reflexes and transcranial magnetic stimulation to delineate their electrophysiological characteristics. Both studies demonstrated that MI shares some characteristics with motor preparation and other additional characteristics with motor execution. They concluded that MI might be seen as a specific form of motor behavior, similar but distinct from both motor preparation and execution. Combining the mutual features of actual execution and MI, this particular type of mental rehearsal may be one potential key to enhance motor learning. Thus, as described before, MI can be applied to a wide range of populations, e.g., to train athletes, musicians or surgeons, but could also be associated with traditional rehabilitation programs of motor functions. In several recent reviews, the authors underlined that specific MI protocol, which could be – or not – associated with movement observation sessions, could improve motor recovery in the affected limbs in people living with the chronic effects of stroke (e.g., McEwen et al., 2009; Mulder, 2007).

CONDITIONS REQUIRED BY MI TRAINING DURING MOTOR REHABILITATION

First, we must investigate whether the consequences of stroke still enables patients to mentally perform some of the movements they are no longer able to actually execute (Johnson, 2000). Many patients with hemiparesis or hemiplegia preserve the ability to represent themselves grasping an object with their impaired limb. This is a strong argument for programming MI sessions, if not during the acute phase, at least within the chronic period with the aim to facilitate functional reorganization. However, clinicians should control the exact extent of the lesion with accurate cerebral neuroimaging techniques, to provide a diagnosis of what could be exactly mentally performed by the patients. This ability may be impaired in case of right posterior parietal or left frontal lesions, known as being integrated in a network of interconnected areas distributed throughout parietal and frontal regions. One of the most important skills to recover after stroke is acting within the haptic space to make grasping available. Grasping an object remains nevertheless different from using this object. Tool use engages a left hemispheric network including frontal, temporal and parietal regions and patients with left brain lesions exhibit apraxia, i.e., deficits when demonstrating how a single tool should be used. This is an important issue as MI should be based on goal-directed movement to make this exercise meaningful for patients. Tool impairment reveals little overlap of cerebral regions with those controlling grasping. These two motor functions remain nevertheless linked together as choosing a functional grasping movement depends on the goal of the task and the online information about the object's structure and orientation (Randerath et al., 2010). Thus, patients exhibiting such cerebral lesions are probably not the best candidates for being involved in a MI rehabilitation program. According to Simmons et al. (2008), almost 40% of the patients are unable to perform MI after stroke. Although inter-individual differences in MI abilities were high, due to the various features and consequences of stroke, this observation would probably prevent from programming MI sessions for such patients or, at least, this is an indication for postponing mental work after some potential recovery due to cerebral plasticity (Cramer, 2008; Rossini and Dal Forno, 2004). Despite this, Zimmerman-Schlatter et al. (2008) reviewed studies focusing on the efficacy of MI in post-stroke rehabilitation, and concluded that MI provides additional benefits to conventional physiotherapy. Another concern is related to the involvement of primary motor cortex in MI as it is at the interface between the operations of movement preparation and execution (Dechent et al., 2004). After stroke, the movements opposite to the stroke side, whenever possible, activate the contralateral primary motor cortex, as also observed in healthy participants. Simultaneously, the same movement was shown to activate the ipsilateral motor area, i.e., that of the unaffected hemisphere (Ward et al., 2003; Calautti et al., 2007). The extent to which this could impair the MI function remains rather unknown. As underlined by Sharma et al. (2009), the motor system, including the ipsilesional primary motor cortex, is activated by MI in well-recovered patients after subcortical stroke. There remains, however, a suspicion of cerebral disorganization with reference to residual motor impairment and within this context, the effect of MI training may potentially be weakened. The main factors that determine the use of MI and the quality of the results to be expected were recently described by Dijkerman et al. (2010). Among them, the authors outlined the severity of motor impairment, the time since onset of motor impairment, the cognitive impairments and, of

course, the ability to form mental images. We nevertheless keep the possibility to evaluate the quality of MI by using other indirect indicators, e.g., behavioral outcomes. The measure of behavior is based on the functional equivalence between the actual execution of the movement and its mental representation. The pace at which MI is performed closely resembled that of actual execution. It is easy to measure the time of a mental representation. The principle of isochrony is ideally applicable to motor sequences lasting from 10 to 20 seconds. Knowing the actual movement duration, the comparison with the time needed to mentally perform the same sequence provides information about the participant's ability to preserve the temporal characteristics of the movement. Above and below these boundaries, time is distorted (Guillot and Collet, 2005). Forming a vivid image of a very short movement requires time and, therefore, the actual duration is frequently overestimated. Conversely, a very long motor sequence is likely to be shortened when rehearsed, especially if it is rhythmic or repetitive, e.g., walking along long distances. Keeping these particular cases in mind, measuring the time needed to mentally perform a movement is one of the easiest means for the evaluation of MI quality (Malouin et al., 2008). Due to general motor impairment after stroke, however, it may be assumed that the principle of isochrony will be changed in stroke patients. Wu et al. (2010) clearly showed that participants required significantly more time to physically practice than to mentally perform tasks, on the one hand. On the other, stroke also drastically affected MI as a significant greater amount of time for mental practice of the more-affected arm than for the less-affected arm was also observed. Mental chronometry could thus be used to assess the severity of stroke and to evaluate how patients improve movement timing along the rehabilitation process.

FEEDBACK INFORMATION DURING ACTUAL EXECUTION, MI AND AFTER DEAFFERENTATION / DEEFFERENTATION

An important concern is related to the somesthetic peripheral information which is not longer available in patients with stroke. Such information is however needed to perform a movement adequately and, consequently, an accurate mental representation. The mental representation of an action is probably one of the first steps before its actual execution. At least, the individual should represent the main goal of the movement and the own consequences of the action (in terms of result or motor performance). This is associated with some expected sensorial perception which is recalled from the procedural long term memory and serves as reference for the forthcoming execution. The well known contribution from Schmidt (1975) was updated in 2003 and stated that during the preparation phase, the individual could predict the expected feedback, either visual or somesthetic, that the actual movement should provide (Schmidt, 2003). The movement is considered well-done when the expected information matches the actual outcome. In contrast, when the actual feedback mismatch the expected feedback, the individual could consider, with the help of his (her) trainer or teacher, that the actual execution is better or worse than the previous one. In the first case, he (she) should memorize the new execution recognized as being more efficient. In the second, he (she) might consider that the actual execution should not be memorized as a new model of movement and should, at least, just be seen as an experience that should not be repeated in forthcoming trials. In the particular case of MI, sensorial information related to

movement execution can be recalled without any overt execution according to a ‘top-down’ operation. Such information, corresponding to the expected feedback, could however not be compared to actual execution. This is the basis of MI training. While the close relationship between motor processes and imagery is often underlined, stroke patients may not benefit from sensorial feedback. They could just rely on central information that cannot be updated through actual execution. The main role of MI could thus be reduced to the maintenance of motor information in the long term memory across time. If SCI patients are believed to allocate additional cognitive resources to perform MI, they were nevertheless shown to preserve the integrity of motor programs at the central level. Accordingly, Hotz-Boendermaker et al. (2008) provided evidence that not only the MI of foot movement activated the premotor and motor cortex, but also a real attempt to execute the same movement. The authors thus considered that central programs were preserved despite long-term deafferentation / deefferentation. However, Lacourse et al. (1999) previously showed that cortical motor processes were altered by the absence of kinesthetic feedback during attempted movement of a deafferented limb as well as during MI. Whether central programs are preserved seem to be attested by experimental data but another process could work simultaneously to reorganize central networks. The extent to which this reorganization could occur is not known in greater details as, at our own knowledge, only two papers specifically addressed this issue (Jackson et al., 2003; Sacco et al., 2006). On the other hand, somesthetic perception, although altered, is not entirely removed. At least, stroke patients could probably just perceive weakened information remaining from body segments during passive exercise of limbs manipulation by the physiotherapist. In addition, they could also use visual information for controlling movement execution that should usually be controlled through proprioceptive and tactile information. In this latter case, the vision system serves a proprioceptive function. Somesthetic cues are not the only source of available information during actual execution and several papers demonstrated that autonomic nervous system activity is preserved during MI (Decety et al., 1993; Roure et al., 1998; Oishi et al., 2000; Collet and Guillot, 2010). The question of whether autonomic responses during MI could be used by patients to improve motor execution could thus be asked. Heart rate and electrodermal responses are observed as early as the participant is engaged in the mental representation of an action. However, these autonomic responses could not be consciously perceived and we may hypothesize that providing a feedback of what responses the mental rehearsal has elicited might help the patients during the rehabilitation process. Patients could be advised to focus themselves on important features of the movement they should mentally rehearse, and could then read the information displayed online by the physiological dataset. The association between a particular pattern of autonomic responses and the vividness of MI could thus be learnt by the patient, to serve as reference for effective MI. This procedure could be an opportunity to address the removal of sensorial feedback after stroke but also to monitor the quality of MI products in real-time.

Despite the limitations we mentioned about the consequences of central injury on MI ability (possible MI impairments and difficulty to integrate sensorial feedback while being paralyzed), the reference to MI intrinsic properties promotes that MI is a reliable candidate to be integrated into rehabilitation programs. We should now investigate the main pathological fields which are eligible for mental rehearsal.

MI TREATMENT IN PATIENTS WITH STROKE

Taken as a whole, all injuries keeping the patients motionless or require them to rest during the post-surgery period should benefit from mental training. We already described stroke as one of the main injuries which is likely to be treated with MI in association with traditional rehabilitation. Many papers have now demonstrated the beneficial role of MI in motor rehabilitation after stroke. Dickstein et al. (2004) integrated MI sessions for gait rehabilitation in post-stroke hemiparesis. A 69-year-old man with left hemiparesis completed gait practice for a 6-week intervention focused on gait and impairments of the affected lower limb (a 15-minute-MI session, 3days a week). Several kinematics parameters were improved, e.g., 23% increase in gait speed and 13% reduction in double-support time associated with an increase in range of motion of the knee. The same program was applied to 4 persons with chronic hemiparesis and resulted in similar improvements of locomotion and gait (Dunsky et al., 2006). The most recent study by the same team included 17 participants with hemiparesis caused by unilateral stroke. The authors notably found that the walking speed significantly increased by 40% after training (e.g., single-support time of the affected limb and double-support time decreased). Stride length also improved and gains were largely maintained at the 3-week follow-up test (Dunsky et al., 2008). Recovery from stroke also requires the reconstruction of the upper-arm functions and particularly of hand skills. Page et al. (2007) recorded significant clinical changes in the rehabilitation of the affected arm in patients with chronic stroke using a program incorporating mental practice. Based on the hypothesis that MI is more effective when combined with task-specific practice, the authors requested 10 chronic stroke patients to complete 30-minutes sessions of mental practice directly after usual therapy. The dependent variables included two specific tests focused on manual abilities and clinical evaluation of daily task activities. After intervention, participants exhibited substantial improvement in both tests and significant performance gains in daily tasks. Interestingly, fMRI data in the follow-up period revealed significant increases in activation to wrist flexion and extension of the affected hand in the premotor area and primary motor cortex ipsilateral and contralateral to the affected hand, as well as in the superior parietal cortex ipsilateral to the affected hand. The authors attributed these changes to cerebral plasticity elicited by the therapy program and this was probably one of the first study exhibiting changes in the cortical maps in response to MI practice since the contribution of Pascual-Leone et al. (1995). Iestwaart et al. (2011) obtained more mitigated results by investigating the potential therapeutic benefit of MI in stroke patients with persistent upper-limb weakness. The study analyzed the outcome of 3 groups of participants: i) 39 patients were involved in 4 weeks of mental rehearsal of upper limb movements during 45-min supervised sessions three times a week and structured independent sessions twice a week, ii) the second group included 31 patients who performed equally intensive non-motor mental rehearsal, and iii) 32 patients received normal care without additional training. No difference between the treatment groups was found on the Action Research Arm Test (Lyle, 1981) or on any of the secondary outcome measures. The authors concluded that mental practice with MI does not necessarily enhance motor recovery during the early post-stroke period, at least if actual practice is not associated with the mental work. In light of such data, it remains to be seen whether mental practice with MI is an effective rehabilitation technique, or at least determine what the prerequisites to ensure its effectiveness are. It also remains to analyze the

content of mental rehearsal sessions as several differences could easily be seen when comparing experimental designs. Most tasks involved mentally rehearsed movements of upper or lower limbs. However, tasks included either single movement involving a limited number of muscles (flexion or extension), non goal-directed movements, or even movements with a clear objective close to that of daily life. Intervention period also varied from 2 to 6 weeks, while the frequency of MI sessions ranged from multiple sessions per day, up to 3 times a week. The dependent variables clearly differed with regards to patients' characteristics. There was some evidence that additional MI intervention has positive effects on arm recovery function after stroke. However, as underlined by Braun et al. (2006), no definitive conclusion could be drawn except that further research is needed with particular attention to the definition of mental training content (especially the type of MI which is believed the more effective, i.e., visual and/or kinesthetic) and standardized measurement of outcome. Several studies provided evidence that mental rehearsal of movement can elicit effects that normally result from actual practice. One of the most positive results is that MI intervention may elicit plasticity in the brain (Pascual-Leone et al., 1995). Despite changes in brain activation, it may be hypothesized that these have not elicited changes at the behavioral level yet. Variations in brain activity might thus not directly promote changes at the behavioral level and additional time might be needed to observe behavioral transformation. It seems obvious that further investigations should determine the appropriate load and the relative ratio of both physical and MI practice. This issue was recently addressed in a review paper by Schuster et al. (2011) with a specific exploration of what is actually done in 5 domains of activity using MI including clinical applications. Finally, one of the neglected MI properties is its ability to deal with psychological problem solving, by improving self-confidence and managing stress. Because of the urgency to deal with the motor consequences of stroke, it is common that the question of patients' psychological state is ignored. Yet, it seems clear that persons with stroke are truly stressed by the alteration of their physical integrity. The more severe the injury and longer the recovery period of rehabilitation, the more prolonged and important the mood disturbance may be, with potential consequences on motivation to recover motor function, at least partially. After experiencing stroke, the patients could feel several negative emotions including isolation (restricted relationships with family and friends), frustration (awareness of both the alteration of physical abilities and the difficulty or inability to recover mobility), and mood disturbance (the patient may temporarily be depressed, or become upset by minor annoyances). MI may have psychological therapeutic effects related to stress management and relaxation. The possibility of starting imagery, even during the acute phase, by focusing the patients on positive and relaxing images could be a fruitful preparation for the subsequent physical rehabilitation. Two theoretical models of MI, originally designed for sport performance, integrated the emotional dimension, i.e., the PETTLEP model by Holmes and Collins (2001 – P for Physical, E for Environment, T for Task and Timing, L for learning, E for Emotion and P for Perspective) and the MIIMS model by Guillot and Collet (2008 – Motor Imagery Integrative Model in Sport). In the first model, the authors hypothesized that including realistic emotional scenarios in the imagery instructions is likely to make imagery much more evocative and closer to real-life situations. Therefore, this should lead to a more vivid imagery experience. The MIIMS describes 4 domains of intervention for MI. Among them, there is a specific field in which MI may have a psychological outcome by controlling stress, improving self-confidence and enhancing motivation. These are dimensions which should now have a rehabilitation function due to the

particular psychological state the patients should undergo. MI has thus the potential to act at both levels, i.e., that of motor recovery with rehabilitation training and that of the more extensive psychological status of patients (decreasing stress and increasing well-being).

MI TREATMENT IN PATIENTS WITH SPINAL CORD INJURY

Although brain and SCI are related to different causes, the main consequences result in the paralysis of limbs or, at least, in severe alteration of motor functions (e.g., gait, locomotion, grasping). Low SCI paralyzes the lower limbs (paraplegia) while injury of the spinal cord at the level of cerebral vertebra results in both lower and upper-limbs paralysis (quadri- or tetraplegia). Paraplegia is observed in case of SCI at the level of the second lumbar vertebra or below (thus with specific motor deficits). Tetraplegia also results in several levels of injury with different motor consequences. Trauma at the fifth/sixth cervical vertebra could lead to severe paralysis of the four limbs whereas at the sixth/seventh cervical vertebra, some upper-limbs functions could be preserved, e.g., extension of the forearm. At our own knowledge, the first study focusing on MI after SCI is from Decety and Boisson (1990). They took movement time as the main dependent variable and observed that movement times in the group of paraplegic and tetraplegic patients did not differ from those of healthy participants. The authors reported that the patients felt a sensation of subjective effort accompanying mental rehearsal and used this observation to claim that MI should be compatible with rehabilitation. At the neurophysiological level, there is no discussion about whether cognitive functions may be impaired by SCI. This was later confirmed by Hotz-Boendermaker et al. (2008) as patients with complete SCI could nevertheless perform the mental representation of a movement involving a paralyzed body segment but could also attempt to perform this movement. Both operations were shown to elicit cortical activation, thus giving some evident support to motor program preservation despite both deafferentation and deafferentation. Sabbah et al. (2002) confirmed that, even several years after SCI from the sixth thoracic to the first lumbar vertebra, the activation of lower limb cortical networks can be generated either by the attempt to move, the mental evocation of the action, or the visual feedback of passive somesthetic stimulation. Nevertheless, Lacourse et al. (1999) underlined that, due to the absence of sensory feedback from the deafferented limbs, some variability in central motor processing could occur. The assumption that compensatory information originated from visual information could overcome the lack of somesthetic clues has not yet been tested (see the above paragraph *"Feedback information from actual execution, MI and after deafferentation/deafferentation"*). From a pragmatic viewpoint, how MI might contribute to promote the motor rehabilitation of SCI patients? Only few studies addressed this issue, by testing whether MI practice can improve motor function. There are no extensive studies which would have covered a large number of patients but only several case studies or groups with a small number of patients who completed an individualized MI intervention. Grangeon et al. (2011, submitted) applied a 5-week MI training program to a male patient injured at the C6-C7 level. He exhibited high MI abilities that would have probably favored significant improvement of motor function. Indeed, he considerably improved speed and accuracy of a reaching and grasping sequence with his dominant arm. Despite the enhancement of intrinsic movement speed, the improvement of movement

smoothness was also a factor that highly contributed to decrease movement time. MI sessions were made of single movements representation such as arm flexion and extension further associated with movement needed for daily-life activities, e.g., extending the forearm towards a target to be reached and seized. The MI program was combined with classical sessions of physiotherapy and ergotherapy. The patient also significantly improved normative and validated tests, e.g., the Minnesota and Box and Blocks tests. Due to the weakness of muscles controlling digit flexion, the patient was guided to learn another coordination requiring a new plan for muscles cooperation. When extending the arm towards the target to be reached and grasped (e.g., a glass), the patient was instructed to keep his wrist flexed. As early as his hand came into contact with the glass, he was requested to extend his wrist, this movement being passively helped by hand contact on the glass associated with the weight of the upper-limb. The wrist extension automatically triggered fingers flexion, thus enabling to grasp the glass. Once the glass was held, the patient should maintain his wrist extended to ensure keeping the grasp during enough time to bring it to his mouth. Maintaining the glass was crucial as this sequence required the patient to keep attention highly focused on wrist extension. This was trained specifically with MI. This new coordination, called tenodesis, was learnt by combining both actual and mental practice. Data therefore suggest that MI practice contributed to successfully achieve the programming of new upper limb coordination. In this case, the new action has been built up without somesthetic feedback but probably with the help of visual feedback.

When the SCI is at the level of fifth cervical vertebra, the patient can no more extend his arm. Surgery may help to overcome this impairment with the solution of tendon transfer technique. As the biceps remains controlled voluntarily, the surgery consists in taking a part of the long biceps tendon to graft it onto the triceps tendon. Therefore, arm extension becomes possible again, although long and hard rehabilitation is required. To test the effectiveness of MI, Grangeon et al. (2010) implemented MI sessions into physical reeducation to a patient who underwent tendon transfer. Both sides were grafted (dominant arm first). The rehabilitation program was made of two distinct sessions, first the physical practice during a two-week-period, then the MI practice during the same duration. The reversed schedule was completed for the other arm. While the combination of MI and physical training significantly contributed to improve the kinematics of pointing a target place just in front of the patient, there was no order effect as performance of both sides did not differ one from another. MI was therefore believed to favor central networks reorganization after tendon transfer, thus making a part of a flexor muscle acting as an extensor. This result should be emphasized by analyzing the time course of cerebral activation changes along with the modification of muscle functions. Here again, MI might play a crucial role in the process of neuronal plasticity (Pascual-Leone et al., 1995). This could be favored and enhanced by determining the most efficient content for mental rehearsal. In a very-well documented review, Malouin and Richards (2010) recently proposed a set of rules for MI practice which should be followed by clinicians with the aim to elicit the most expected effect on motor rehabilitation. The authors advised that i) clinicians should be aware that it is imperative to evaluate MI ability before introducing mental practice, ii) patients who initially demonstrate difficulty in generating mental representation of movements eventually may improve their MI ability with repeated exposures, iii) the lack of somesthetic cues could perhaps be compensated for by additional visual information. With reference to this latter proposition, it should be mentioned that visual information could overcome the lack of information from the

body if it is correctly focused, i.e., on movement sequences that usually require sensory feedback from somesthetic information. In the conclusion section of their paper, Malouin and Richards (2010) underlined that researchers and clinicians should learn more about MI processes that will lead to define MI procedures and accurate clinical guidelines in greater details.

MI TREATMENT IN PATIENTS WITH PERIPHERAL INJURY (JOINT SPRAIN, MUSCLE TEAR, BONE FRACTURE)

Using MI with the aim to improve motor functions after peripheral injury is based on the same rationale as after central injury. There is however a strong difference between the two situations: The peripheral lesions are reversible and there is generally good hope of recovering motor function equivalent to that prior to trauma through surgery and rehabilitation, in all possible forms, including MI. However, using MI in rehabilitation programs after peripheral injury has not been often studied as for cerebral injury. Joint and muscle damages may also cause an immobilization of the patient. The longer it lasts, the more the rehabilitation may be extended and difficult. Again, mental rehearsal can contribute to recover simple movements (flexion, extension, internal or external rotation, abduction or adduction ...), but may also improve more complex motor programs. One of the first experiments addressing this issue is that from Newsom et al. (2003), although the experimental group included healthy participants. The study was conducted to examine the effects of MI on strength loss, after immobilization of the wrist. The experimental group was divided into two subgroups, the first performing mental practice during 2 weeks while the second completed a series of neutral activity which had nothing to do with mental activity and served as control group. Both groups showed force loss after immobilization by comparison to the maximal performance evaluated during the pre-test session. However, performance in the MI training group decreased to a lesser extent than in the control group. Results therefore revealed that MI may contribute to prevent strength loss that occurs during immobilization. Two other important studies may be briefly described to ascertain the role of MI in force gain. Firstly, Yue and Cole (1992) trained healthy participants with mental practice. Two other groups were studied, the control and physical training groups. The maximal isometric force of the abductor muscle of the fifth finger was measured before the participants mentally practiced the same movement. After a rehearsal period of 4-weeks (five sessions per week), the participants were re-tested. The isometric force significantly increased during the retention test by about 30% in the physical training group whereas the improvement was 22% in the imagery training group. As expected, the control group performance remained quite stable by improving 3.7% only. The authors concluded that strength increase could be achieved without repeated muscle activation. These force gains appeared to result from practice effects on central motor planning/programming. Almost the same result was obtained later by Ranganathan et al. (2004) although with additional useful results. The authors concluded that mental training enhanced the cortical output signal, thus driving muscles to higher activation level and increased strength. The important difference with Yue and Cole (1992) study was that a fourth group was trained on upper limb flexion with mental practice, i.e., biceps force. Training sessions lasted for 12 weeks (15 minutes per day, 5 days per

week). At the end of the training session, the group who trained the abductor of the fifth finger had increased its strength by about 35%. The elbow group increased the elbow flexion strength by 13.5% and the physical training group increased the finger abduction strength by 53% (the control group did not exhibit any change, as expected). Thus, force improved as a function of both muscle and training content. The rationale for explaining muscle strength improvement is the enhancement of cerebral motor command which was supposed to recruit more motoneurons to command muscle contraction and to better synchronize the motor units within the same muscle. This process must be qualified as a function of the cortical surface controlling each muscle. The five fingers are known to be represented by almost one third of the motor cortex while the cortical surface controlling the trunk and the lower limbs is about the same. Thus, improvement of muscle force by mental training is proportional to the cortical surface controlling this muscle. Keeping these results in mind, Guillot et al. (2009) tested the effect of MI training in patients with burnt hands. As well, Stenekes et al. (2009) investigated whether MI during the immobilization period after flexor tendon injury resulted in a faster recovery of central mechanisms of hand function. In parallel, Lebon et al. (2011) applied a MI program to participants after surgery of anterior cruciate ligament. Here, we have several experimental examples examining the variable 'type of muscle'.

First, the study by Guillot et al. (2009) aimed at investigating the effects of a 2-week MI training program combined with conventional rehabilitation on the recovery of motor functions in handed burn patients. Fourteen patients were randomly assigned to the imagery or the control group. Three complex manual motor sequences were tested at five intervals during a 5-week medical procedure. Range of motion during wrist extension, fingers dissociation and coordination were evaluated after the rehabilitation program. The results provided evidence that MI facilitated motor recovery, especially at the level of wrist movement. The study by Stenekes et al. (2009) brought more mitigated results. The patients were assigned to a mental training group based on kinesthetic MI of finger flexion movements during the post-operative dynamic splinting period. After the training period, the participants completed a reaction time test related to the preparation time of finger flexion, i.e., they should press a button as fast as possible following a visual stimulus. The other dependent variables were kinematics analysis of drawing, active total motion, and strength. After the immobilization period, the MI group reacted faster than the control group. However, no other significant influence of MI was evidenced on kinematics. As expected, MI positively influenced motor function, albeit with selective efficacy which should probably relate to the content of the mental program. As underlined by the authors, there are some factors that may have led to an underestimation of the MI effects, such as low patient compliance, suboptimal dosage of MI, no case control for injury severity, and small sample size. The MI content and the frequency of sessions training thus appear as being a major concern when testing MI efficacy and represent a key-problem that should be solved shortly. In any case, this is an important issue on which researchers should focus on in due course. The study by Lebon et al. (2011) aimed to assess the therapeutic effects of MI on the activation of lower limb muscles, as well as on the time course of functional recovery after surgery of the anterior cruciate ligament (ACL). Although the cortical surface controlling knee movement is reduced by comparison with upper-limb movement, this study exhibited positive outcomes from MI training. As a working hypothesis, we might assume that the issue related to the cortical surface controlling the muscle to be mentally trained could probably be overcome by the duration of training. Twelve patients with a torn ACL were randomly assigned to a MI or

control group and received usual sessions of physiotherapy. EMG activity of the quadriceps, anthropometrical data, and lower limb motor ability were measured throughout a 12-session-therapy. The data provided evidence that MI elicited greater muscle activation. The authors concluded that the muscle activation increase might originate from a redistribution of the central neuronal activity, as no anthropometric change was observed in lower limb muscles after MI practice. This study confirmed the effectiveness of integrating MI in a rehabilitation process by facilitating muscular properties recovery following motor impairment. MI may thus be considered a reliable adjunct therapy to help injured patients to recover motor functions after reconstructive surgery of ACL. The improvement remains nevertheless selectively focused on factors that are neurophysiological related. Lebon et al. (2011) did not evidence any change at the muscle level and the increase in muscle activation, with no change in muscle size, was attributed to central reorganization. In the same way, the results by Maddison et al. (2011) could be compared to those of Lebon et al. (2011). This imagery intervention improved knee laxity and healing-related neurobiological factors. No structural change was reported at the peripheral level (e.g., increase of muscle size or decrease in joint effusion), thus strengthening the hypothesis that MI influence is selectively confined to central nervous system.

Training schedules integrating MI are believed to keep the motor programs into memory, due to brain plasticity (Pascual-Leone et al., 1995). This contribution should be emphasized in rehabilitation periods during which actual practice is not yet possible, due to immobilization or pain. More precisely, the synchronization of motor units is thought as being the main process improved by mental training, thus preserving, at least partially, muscle strength. Motor units synchronization itself is probably dependent upon central reorganization of cerebral networks controlling movements which are mentally rehearsed. Therefore, if actual practice is needed to build up and store motor programs into long term memory, MI may also play a crucial role in these operations. Due to its intrinsic properties, MI should also have the potential to be beneficial for the elderly. This is a specific population which may be particularly affected by the maintenance of motor function with advancing age. As a consequence of ageing, muscle size decreases as along with range of motion, and such processes may be compounded by the reduction of general motor activity. Postural functions and locomotion may be significantly impaired, thus increasing the risk of falling. Hamel and Lajoie (2005) reported a beneficial effect of MI practice with decrease in both attentional demands and postural oscillations on the antero-posterior axis. The use of a tailored mental practice should therefore enable regular maintenance and preservation of the mobility in the elderly, especially as MI quality evolves with age. Interestingly, Malouin et al. (2010) showed that MI alterations are associated with an age-related decline in visuo-spatial and kinesthetic working memory. MI is thus a good way in maintaining motor potential but also one's own ability to form mental images.

GENERAL CONCLUSION

To conclude, we must first reiterate that MI is not a substitute of the classical course of physical therapy during the rehabilitation process, but rather an adjunction which may bring additional benefits, e.g., among others, saving time and/or improving motor function. This is

an attractive and cost-effective task requiring the patient to engage himself voluntarily and actively in this process. It is actually important to involve patients in the rehabilitation process by making them active. MI is a rather good candidate for that. As a specific cognitive operation, MI remains independent upon residual motor function after central or peripheral injury. Most patients with stroke and patients with peripheral injury should thus be able to use MI of movement that can no longer be physically executed (nevertheless, depending upon their own abilities to form and manipulate mental images). Some periods could be favorable for starting short sessions of MI rehabilitation, e.g., just after the acute phase of stroke or after joint surgery. As previously suggested, MI could be here designed to maintain motivation and manage stress, using positive mental images. Nothing is usually done for rehabilitation within this period, and MI should enable early therapeutic interventions when other rehabilitative treatments remain impossible. In parallel, we also should solve some remaining issues related to MI practice, e.g., the onset of neuropathic pain in a substantial proportion of people with SCI when performing MI (Gustin et al., 2008). We must also improve methods and tools enabling the clinicians to follow-up and evaluate the quality and efficacy of the MI work. We recently proposed an index of MI quality integrating different sub-indices (Collet et al., 2011), including questionnaires and interviews, mental chronometry and several physiological parameters measuring i) the functional state of the patient (physiological activation) and its compliance with mental practice requirements, and ii) the ability to maintain attention on motor rehearsal across time, with the aim to individually determine the exact amount of MI trials that should be programmed with the highest efficiency (electrodermal and heart rate responses being recorded during mental work).

Defining more extensively the general conditions and the rules of MI practice to ensure the effectiveness of MI is one of the most important issues. First, we should define criteria to select the patients who would be most likely to benefit from mental training. Examining the best way to use MI and adjusting its content to the patients' features will certainly be a main focus of research in coming years. Schuster et al. (2011) reviewed the main MI contents that were applied to patients with motor impairment. While the goal of each experimental design was very similar, i.e., selecting the conditions that are likely to provide the best motor improvement, we note the high diversity among programs, both in their content and their frequency of use. Malouin and Richards (2010) recently addressed a series of issues related to how MI should be scheduled. Should patients be lying down and relaxed while listening to the instructions, or, in contrast, should they be more actively engaged in their training? Should they learn to self-monitor their training or being kept under clinical supervision? Despite these outstanding issues, the experimental data described in this review support the hypothesis that MI is a valuable and promising cost-effective technique to enhance recovery after motor impairment.

Chapter 45

NEUROPSYCHOLOGICAL ISSUES IN STROKE REHABILITATION

Robert Ruchinskas¹ and Kelly Blair²

Temple University School of Medicine

²Department of Neuropsychology West Tennessee
Rehabilitation Center Jackson, Tennessee, US

INTRODUCTION

Neuropsychologists perform an important function in the evaluation and treatment of patients who have experienced strokes. The role the neuropsychologist plays with patients and their families varies according to the type and severity of stroke and the patient's current position in the continuum of health-care (e.g., from the acute-care hospital to the inpatient rehabilitation unit/center to the outpatient clinic). Neuropsychologists make contributions to the rehabilitation of stroke patients through activities such as neuropsychological evaluations (ranging from brief bedside assessments to comprehensive multi-hour evaluations), interventions to address the cognitive and emotional impact of stroke, and consultation with the patient, patient's family, and treatment team in defining, accepting, and working toward realistic goals for the rehabilitation process.

Assessment of neurocognitive functioning in stroke patients is crucial as the incidence of cognitive dysfunction can be as high as 70% in patients with recent strokes (Ruchinskas, Singer, and Repetz, 2000; Mast, MacNeill, and Lichtenberg, 1999; Tatemichi, et al., 1994). Even "pure motor" strokes, or those with little evident cognitive impact, will show deficits when properly assessed with a neuropsychological battery (Hinkle, 2002). In addition, the neuropsychological understanding of brain-behavior relationships can assist the patient and treatment team in understanding and conceptualizing changes in cognitive, emotional, and/or behavioral functioning following stroke. This contribution is not dependent on giving a particular test or obtaining a particular evaluation result but instead comes from the neuropsychologist's educational background and ability to assist with comprehensive case conceptualization. Finally, although not a focus of this chapter, the neuropsychologist

contributes much to the overall success of the rehabilitation program by aiding the patient, patient's family, and the treatment team in dealing with the emotional aspects of stroke. This contribution, which the neuropsychologist is uniquely suited to make, is as important as the assessment and intervention process for the cognitive difficulties we discuss below. The neuropsychologist's knowledge base concerning the mechanisms, sequelae, pathology, and outcome of strokes greatly aids in the assessment and treatment of stroke patients in rehabilitation setting and leads to improved patient care.

Although this review covers many of the disorders that can be associated with strokes, it is rare that these conditions are found in isolation. Part of this fact is because strokes are not constrained to any one particular vascular territory or brain region. Each stroke is unique. Another reason for the decreased chance of encountering pure agnosia, apraxia, and visual disorders is due to the nature of rehabilitation admissions and reimbursement. Since walking is often the "gold standard" in terms of deficits that can lead to a rehabilitation admission, disorders that involve little motor weakness or solely upper extremity deficits will have a lesser chance of admission (and subsequent evaluation by the clinician). Hence, while we focus this review on discrete conditions commonly associated with strokes, the neuropsychologist will typically encounter a single patient with aspects of two or more of the syndromes discussed below, as the more neurologically involved patients are more likely to gain admission.

DEFINITIONS AND EPIDEMIOLOGY

Stroke can be defined as the "sudden occurrence of a nonconvulsive, focal neurologic deficit" (Victor and Ropper, 2001, p. 823). The World Health Organization defines stroke as an "acute neurological dysfunction of vascular origin with sudden (within seconds) or at least rapid (within hours) occurrence of symptoms and signs corresponding to the involvement of focal areas of the brain" (World Health Organization, 1989, p. 1412). Although other terms are used to describe this event at times (apoplexy, cerebrovascular accidents [CVA], or shock) stroke is the preferred term (Victor and Ropper, 2001).

Strokes are the most frequent type of cerebrovascular disease. Between 500,000–700,000 persons in the US have a stroke each year (Weinstein and Swenson, 1998). Over three million people in the US experience disability as the result of stroke. Stroke is the third most common cause of death in the US. Although strokes typically occur in those sixty-five years of age and older, twenty-five percent of strokes affect people aged forty-five to sixty-five. During a stroke, reduced blood flow limits the supply of nutrients provided to brain cells, primarily oxygen and glucose. This reduction in nutrient supply leads to cerebral ischemia when blood flow is not sufficient to maintain the cell and to cerebral infarction when the reduced blood flow leads to cell death (Victor and Ropper, 2001).

TYPES OF STROKE

There are two broad categories of stroke: obstructive and hemorrhagic. Obstructive strokes are due to blockages in the cerebral arteries and are of two primary types: thrombotic

and embolic. In thrombotic strokes, atherosclerotic plaques or fat deposits gradually develop within the arteries over time and this leads to narrowing of the vessel, which in turn reduces blood flow. In this type of stroke, symptoms typically develop over several hours to a few days at times. This type of stroke usually affects the middle cerebral arteries and vertebrobasilar arteries (Weinstein and Swenson, 1998). Cerebral atherosclerosis, or narrowing of the blood vessel, is the most common cause of ischemia and infarction. Thrombotic strokes account for approximately 60 percent of all strokes (Victor and Ropper, 2001).

During embolic strokes, material breaks away from an artery wall or foreign matter finds its way into the cerebral arteries and then becomes lodged in the vessel. Approximately twenty percent of all strokes are embolic, with roughly half of them originating from cardiac sources. Taken together, thrombotic and embolic strokes account for over 80% of first strokes (Terent, 1993). In contrast, in hemorrhagic strokes, the blood vessel bleeds onto the brain tissue. Typically, with hemorrhagic strokes, the vessel ruptures and there is the sudden onset of symptoms. Primary intracerebral hemorrhage is the third most common cause of stroke (after thrombotic and embolic strokes) and is most often due to hypertension. Intracerebral hemorrhages account for approximately 11% of first strokes (Caplan and Moelter, 2000).

Subarachnoid hemorrhage is the fourth most common type of stroke. Subarachnoid hemorrhages are typically caused by a ruptured aneurysm. However, other sources, such as arteriovenous malformations, which are congenitally abnormal blood vessels with abnormal blood flow that are susceptible to leakage, are less commonly the cause of hemorrhagic stroke. Subarachnoid hemorrhages account for approximately 6% of hemorrhagic strokes (Victor and Ropper, 2001).

Compared to obstructive strokes, hemorrhagic strokes are much more fatal in the short term. During the first month following stroke, 52% of persons with intracerebral hemorrhage will die, 45% of persons with subarachnoid hemorrhages will die, and 10% of persons with thrombotic-embolic strokes will die. The long-term outcome of obstructive and hemorrhagic strokes is similar, despite the differences in early mortality and incidence of these two types of strokes (Bamford, Dennis, Sandercock, Burn, and Warlow, 1990).

Transient ischemic attacks (TIAs) differ from strokes in that the symptoms produced by TIAs do not persist and are typically reversed in minutes to hours. In TIAs, the episodes of impairment typically last up to 15 minutes and fully resolve within one day. Approximately one-third of persons who experience a TIA will ultimately experience a stroke (Lezak, Howieson, Loring, Hannay, and Fisher, 2004). Reversible ischemic neurologic deficits (RINDs) are similar to TIAs in that the symptoms are transient and fully resolve. However, the symptoms in RINDs last from one day up to 3 weeks, versus the one-day resolution of symptoms in the TIAs.

MAJOR ARTERIES/BLOOD SUPPLY TO THE BRAIN

Two carotid arteries and two vertebral arteries irrigate the brain. The carotid system provides blood for the frontal and parietal lobes, two-thirds of the temporal lobes, hypothalamus, basal ganglia, and eyes. The internal carotid arteries' major branches are the anterior cerebral artery and middle cerebral artery. These arteries provide blood to anterior

and middle portions of brain. The middle cerebral artery is largest supplier of blood to the cerebrum. The minor branches of the internal carotid arteries include the ophthalmic artery, anterior choroidal artery, posterior communicating artery, and anterior communicating artery. These minor branches of the internal carotid artery provide blood to various subcortical regions.

The vertebral system supplies the posterior temporal lobe, occipital lobe, and upper part of spinal cord, brainstem, midbrain, thalamus, cerebellum, and inner ear (Joseph, 1990). The vertebral arteries join to form the basilar artery. The major branches of the vertebral arteries are the basilar artery and posterior cerebral artery and they supply parts of the temporal and occipital lobes. The minor branches of the vertebral arteries (the anterior and posterior inferior cerebellar arteries) interconnect to form the circle of Willis. This formation helps the brain compensate if blockage of vertebral or carotid artery occurs on one side of the brain.

REGIONAL SYNDROMES FOLLOWING STROKE

A stroke limited to the anterior cerebral artery is rare. Symptoms seen with this type stroke are usually part of the symptomatology of middle cerebral artery strokes. Anterior cerebral artery stroke symptoms include contralateral lower extremity motor impairment with relative sparing of upper extremity functioning. Other symptoms may include incontinence, motor aphasia, and behavioral/affective changes.

The middle cerebral artery has the largest distribution area of any cerebral artery. Symptoms following middle cerebral artery strokes typically include contralateral hemiplegia of face, arms, and legs; hemisensory deficits; and loss of vision in the visual field contralateral to the lesion. Various forms of aphasia may occur following a left hemisphere middle cerebral artery stroke. Typical symptoms following a right hemisphere middle cerebral artery stroke include visual-spatial and constructional deficits, impaired attentional processes, unawareness of deficits, and impaired understanding of emotional components of language. Middle cerebral artery strokes usually are more rapid in onset and result in greater disability than other types of strokes. Visual field cuts following middle cerebral artery strokes are common.

Internal carotid artery strokes pose the greatest risk to watershed regions (border-zone) of brain irrigation. Deficits depend of the part of the artery most affected although one usually sees effects similar to middle cerebral artery strokes. Posterior cerebral artery strokes typically result in sensory loss, oculomotor palsy, and cerebellar ataxia. Cortical aspects of posterior cerebral artery strokes may include loss of color vision, tunnel vision, alexia without agraphia, and memory impairment.

APHASIA

Aphasia is an acquired impairment of language (speech, writing, and/or reading) due to an injury to the brain (for reviews, see Beeson and Rapcsak, 1998; Kolb and Whishaw, 2003; Benson, 1993). Aphasia (sometimes referred to as dysphasia) is typically produced by left hemisphere damage. Aphasia is a central language disorder and affects not only spoken

language but also, for the majority of cases, writing and reading. Paraphasic errors, which are errors leading to sound substitutions and incorrect word choices, are common features of aphasia. Within the area of language impairment, agraphia refers to a writing impairment and alexia to a reading impairment.

Because approximately 95% of right-handed and 70% of left-handed people are left hemisphere dominant for language, aphasia typically results from a lesion to the left hemisphere. Aphasia may result from right hemisphere damage for left-handed persons. Crossed aphasia is a rare condition in which right-handed people develop aphasia following right hemisphere damage.

In categorizing aphasias, a useful framework is to divide aphasias into fluent aphasias versus nonfluent aphasias. Within each category there are several types. In the aphasias discussed below, the lesion location thought to be important in the production of aphasia syndromes will be highlighted. For a recent review of the anatomy of aphasia, please see Kreisler et al. (2000).

Fluent Aphasia

The fluent aphasias are characterized by fluent speech production in conversational speech, although there can be significant paraphasias. One type of fluent aphasia is Wernicke's aphasia; also known as "sensory aphasia". In this type of aphasia, neologisms and paraphasias characterize the fluent speech output that is produced. Impairments are demonstrated in written and auditory comprehension as well as repetition. Impairment is also usually present in naming, and cueing for naming is rarely of benefit. In this type of aphasia, speech output may be meaningless and the term "jargon aphasia" may be used to describe it. Typically large posterior superior temporal gyrus lesions produce this type aphasia (Benson, 1993).

Another type of fluent aphasia is transcortical sensory aphasia. In this type of aphasia, verbal output is fluent but paraphasias are frequent. Language comprehension is impaired but repetition is intact. Echolalia is a common feature of this type aphasia. Naming, writing, and reading are also impaired. Lesions in the parietal and temporal areas that are posterior to the perisylvian region typically produce this type aphasia.

A third type of fluent aphasia is conduction aphasia. In this type of aphasia, speech output is fluent but is characterized by paraphasias. Comprehension is relatively intact, although there is a significant impairment in repetition and object naming. Lesions producing this type aphasia are often below the supramarginal gyrus in the white matter (arcuate fasciculus), although there may be lesions outside this area. The lesions disconnect intact motor speech areas from intact comprehension areas.

A fourth type of fluent aphasia is anomic aphasia. The distinguishing feature of this type aphasia is severely impaired naming. Speech output is fluent and little or no paraphasias are present. Both repetition and comprehension remain intact. Empty but lengthy verbal output is noted. The lesion is often in the angular gyrus or inferior temporal regions but the lesion may also be found anywhere in language area and even in right hemisphere at times. In this type of aphasia, noun-finding deficits typically originate from damage in the temporal cortex while verb-finding deficits typically are caused by left frontal injuries.

Nonfluent Aphasia

Nonfluent aphasia is characterized by difficulty with the ease/fluency of speech output. As with fluent aphasia, there are several types of nonfluent aphasia. Broca's aphasia, also known as motor or expressive aphasia is characterized by nonfluent speech output with relatively intact comprehension. Repetition skills are impaired but not as impaired as conversational expression. In this condition, although object naming is poor, cueing provides a significant benefit. This was the first recognized aphasia syndrome. Lesions producing this type aphasia are typically in the superior division of the middle cerebral artery in the dominant frontal region with at times lesion extension into the basal ganglia.

A second type of nonfluent aphasia is transcortical motor aphasia. In this type aphasia, verbal output is nonfluent but echolalia can occur. Both comprehension and repetition are generally adequate. Persons with this type aphasia typically do not attempt to spontaneously produce speech. Naming is relatively intact. Damage in the frontal/prefrontal region of the dominant cerebral hemisphere is typically involved, either superior or anterior to Broca's area and often in the watershed zone between the anterior and middle cerebral arteries. In supplementary motor area aphasia, the language deficits produced are identical to those produced in transcortical motor aphasia. However, the lesion that produces this type aphasia is in the dominant medial frontal area.

Another variant of nonfluent aphasia is mixed transcortical aphasia, also known as "isolation syndrome". In this type of aphasia, speech production is nonfluent and conversational speech is similar to Broca's aphasia. Comprehension is also impaired but repetition is relatively intact. Naming is also impaired. The lesion that produces this type aphasia is usually diffuse or multifocal. This results in the isolation of the perisylvian language zone from the surrounding cortical areas.

A final type of nonfluent aphasia is global aphasia. In this type aphasia, all language components are impaired. This includes speech production/output, comprehension, repetition, reading, writing, and naming. Lesions producing this type aphasia are extensive and typically there is involvement of the entire perisylvian language zone. In global aphasia, even if the patient receives long-term speech therapy, the person is rarely able to recover useable language functioning (Strub and Black, 1988).

Pure Aphasia

In addition to the fluent and nonfluent aphasia discussed above, there are also some conditions described as "pure" aphasia. In these conditions, only a specific language function is impaired. One type of pure aphasia is alexia without agraphia. This represents an impairment in reading in the absence of other symptoms of aphasia. This condition is typically produced by left occipital infarctions in the territory of the posterior cerebral artery.

A second type of pure aphasia is pure word deafness. In this condition, although reading, spontaneous speech, and naming are intact, there is impaired comprehension for spoken language and impaired repetition. This is a rare syndrome that typically results from bilateral temporal lobe lesions or a unilateral deep left temporal lobe lesion.

In addition to the cortical aphasia described above, aphasia can also result from subcortical damage. In subcortical aphasia, the onset of symptoms is acute and the patient is

typically mute. In this condition, the patient usually recovers to the point of slow speech output that is poorly articulated and paraphasic with repetition intact. Subcortical aphasia often resembles the transcortical aphasia because of the preserved repetition. Other language features vary widely and there is a tendency for this type of aphasia to fully resolve. This condition includes thalamic aphasia and syndromes associated with damage to basal ganglia and white matter pathways (Crosson, 1992).

Although the above discussion of aphasia focuses on left hemisphere lesions producing aphasia syndromes, the right hemisphere (nondominant hemisphere) also contributes to language function. The right hemisphere appears to have reasonably good auditory comprehension of language as well as some involvement in the spatial components of reading and writing. However, the right hemisphere typically involves little or no speech output. Although the right hemisphere is able to recognize words, it is not able to understand grammar rules and structure or the so-called “pragmatic” aspects of speech (Kolb and Whishaw, 2003). In addition, the right hemisphere appears to play a part in “how” speech is expressed that contrasts the left hemisphere’s focus on “what” is spoken. In fact, Mesulam (2000) argues for a right hemisphere system that parallels the aphasic disorders discussed above, with the expression and reception of prosody, emotional valence, and humor as the basis for the disturbance. Because of a reduction in prosody, individuals with right hemisphere deficits often have monotone verbal production that may be inaccurately interpreted by staff members and/or family members as reflective of depressed mood.

Assessment of Aphasia and Recovery

During the acute phase of stroke treatment, assessment is typically limited to bedside evaluations. These evaluations should focus on conversational speech production, comprehension for auditory material, repetition, and naming as well as a brief assessment of reading and writing. Often, this type of evaluation must be completed at the bedside through brief screening tests due to the impairments in comprehension or expression that accompany acute strokes.

There are several standardized tests for aphasia but they are not designed for bedside use. These more comprehensive assessment batteries are best utilized once the patient is no longer in the acute stage of injury. Included in the list of more comprehensive aphasia test batteries are the Boston Diagnostic Aphasia Examination (Goodglass and Kaplan, 2001), Western Aphasia Battery (Kertesz, 1982), Multilingual Aphasia Examination (Benton, deHamsher, and Siven, 1994), and Aphasia Diagnostic Profiles (Helm-Estabrooks, 1992). There are some single domain tests that are also quite useful in aphasia assessment. These include the Boston Naming Test (Kaplan, Goodglass, and Weintraub, 2001) for naming, the Token Test from the Multilingual Aphasia Examination for comprehension, and the Psycholinguistic Assessment of Language Processing in Aphasia (Kay, Lesser, and Coulthart, 1992) for reading and writing. For a thorough discussion of the variety of measures that can be used both during the acute and post-acute phase in aphasia assessment, please see Lezak et al. (2004) as well as other pertinent chapters in this volume.

During the first month after stroke, significant spontaneous recovery typically occurs with ongoing but less dramatic recovery occurring for several months to approximately a year. Spontaneous recovery of comprehension is typically more complete than spontaneous

recovery of speech output (Benson, 1993). It has typically been thought that most recovery from aphasia occurred by one year after stroke. However, recent research indicates that new treatments that involve motor activation theories (similar to constraint induced movement therapy) can provide significant benefit in aphasia recovery even for patients who are several years post-stroke (Pulvermuller et al., 2001).

In the inpatient rehab setting, interventions to address aphasia are primarily conducted by the speech-language pathologist. The speech therapist may use a variety of remediation and compensation strategies to address targeted aphasia deficits. Aphasia treatment beginning in the acute phase of recovery results in nearly twice the beneficial effect seen solely from spontaneous recovery. Treatment that begins after the acute phase has passed achieves a smaller, but notable effect. Therapeutic interventions designed to improve speech output are typically more successful than those designed to improve comprehension (Albert, 1998). Various strategies are used in aphasia treatment. These include output-focused therapy, melodic intonation therapy, psycholinguistic approaches, cognitive neurorehabilitation, and computer aided therapy. Many aphasias tend to ultimately evolve into some degree of an anomic aphasia, which is not surprising given the large perisylvian areas that have been implicated in the process of confrontational naming.

The less severe forms of aphasia discussed above may not be seen in the inpatient rehabilitation setting because the physical deficits produced from such lesions may not be of the magnitude to produce the physical impairments necessary to qualify for inpatient rehabilitation treatment. In working with aphasic patients in the inpatient rehabilitation setting it is important to work in coordination with the therapists, especially the speech therapists, to insure consistency of approach in allowing the patient to communicate by the most effective means possible. Even when the patient has significant aphasia, it is often possible to develop communication strategies with the patient that will allow for significant information exchange to occur. This not only helps the examiner determine more broadly the cognitive and emotional impact of stroke on the patient, it also helps the patient increase his/her sense of comfort and control knowing that his/her needs and desires can be communicated and understood. Patients can be severely aphasic but appear quite functional in terms of their rehabilitation therapies. Close observation and assessment usually reveals that such individuals are quite adept at picking up on visual and prosodic cues ("I know that they are commanding me to do something over there"). Both the exact level of comprehension and the compensation techniques utilized are essential to communicate to staff and family to help them understand exactly what can and cannot be communicated to the aphasic patient.

HEMIPARESIS AND OTHER MOTORIC DISORDERS

Muscle weakness, discoordination, and/or some degree of paresis are often seen in stroke patients. As the criteria for admission to inpatient rehabilitation often requires motor system dysfunction, the practicing neuropsychologist should be familiar with the causes and effects of hemiparesis and other motoric disorders. Some degree of hemiparesis can accompany lesions that occur anywhere along the corticospinal and corticobulbar tracts in the brain. Thus, damage to the brainstem, pons, midbrain area, white matter tracts of the subcortex, thalamus, basal ganglia, cerebellum, and motor and parietal cortices can all cause paresis

(Victor and Ropper, 2001). In addition, damage to supplementary motor cortices, while not causing paralysis, *per se*, can greatly interfere with the initiation and planning of motor movements. Luria (1966) described a wide variety of initiation and imitation tasks to assess motor planning skills, praxis, and the ability of other behavioral systems (vision, speech) to aid or hinder the accurate performance of motor movements. Luria suggested that damage to the premotor regions would cause both motor incoordination and “efferent motor” perseveration, secondary to disinhibition of primitive automatic movements. The degree of disturbance in a patient’s ability to switch smoothly from one motor movement to another was taken as a sign of the extent of cortical damage. Malloy, Webster, and Russell (1985) found that perseveration on Lurian motor tasks, while occurring more frequently in patients with frontal lesions, also was quite common in individuals with posterior lesions. Ruchinskas and Giuliano (2003) also found that the presence of motor incoordination and perseveration after stroke were quite common and more indicative of global brain integrity than of damage to any particular cortical area, *per se*. At the other end of the spectrum, damage to some areas, particularly the frontal cortex and the caudate region in the subcortex, can cause a lack of spontaneous motor movements (akinesia) in the presence of relatively preserved motor strength (Kumral, Evyapan, and Balkir, 1999). We have observed individuals who will not actively move a limb on command, but will show spontaneous (and purposeful) movement in more unplanned or reflexive actions (e.g., catching a rubber ball being thrown to them). Akinesia also can be present in neglect syndromes and must also be distinguished from the apraxic syndromes listed below.

Perhaps the most effective treatment of any disorders that are discussed in this chapter falls within the arena of the treatment of hemiparesis. Constraint-induced movement therapy, a treatment where the unaffected limb is restrained and a series of shaping paradigms are used to reduce the learned nonuse of the affected (usually upper) extremity, has shown tremendous promise in the rehabilitation literature and in practice (Taub and Uswatte, 2003). While the original design was for long periods of restraint (i.e., 6 hours or more per day), some research has suggested benefit from shorter duration (3 hours per day) of this treatment (Sterr et al., 2002). Taub (2004) reports extension of this treatment to other chronic disabling conditions such as weakness after traumatic brain injury, cerebral palsy, and spinal cord injury. While originally designed for the treatment of nonuse of an extremity after one year, this technique is increasingly being used in acute stroke settings and even as part of home therapy programs, although the efficacy research on which to base these practices is small (Pierce et al., 2003; Dromerick, Edwards, and Hahn, 2000).

APRAXIA

Apraxia is an acquired disorder that negatively impacts the ability to complete learned movements and motor sequences. The deficits in apraxia are not due to impairments in sensation, coordination, strength, or lack of comprehension. Although the types of tasks used to assess the various forms of apraxia will be discussed below, it is important that the patient receives a thorough examination to insure other motor, sensory, language, or cognitive problems are not causing the observed dysfunction. Deficits seen in apraxia are considered high-level motor disturbances that are due to problems with motor planning and in completing the integrative steps that are necessary to complete skilled movements. Apraxia

negatively affects the ability to execute and select changes in body position. In order to complete skilled movements correctly, both conceptual knowledge and production knowledge are required (Heilman, Watson, and Gonzalez-Rothi, 1998).

Control of praxic movements in right-handed people is in the left (language dominant) hemisphere. In left-handed people, the right hemisphere usually controls praxic movements, even when language dominance is on the left. Handedness is more closely related to skilled movement than is language dominance (Strub and Black, 1988). In right-handed people, apraxia is almost never produced by right hemisphere lesions (Heilman and Gonzalez-Rothi, 1993). Damage to subcortical structures may also be necessary for the expression of marked apraxia. For example, a recent study suggests that cortical and subcortical structures provide differential contribution to praxis and the deficits seen in apraxia (Hanna-Pladdy, Heilman, and Foundas, 2001).

Praxis is conceptualized along a continuum of difficulty in performing skilled motor tasks. Completing the tasks to only verbal command is the most difficult. This is done without giving nonverbal cues and without using the object itself. If the patient cannot complete the action following verbal command, then the examiner can attempt to have the patient complete the action by using imitation. Using the real object itself provides the patient with the least difficult scenario.

In theory, performing the action to command only involves the dominant hemisphere's language function. This information then travels to the supramarginal gyrus. Words are subsequently associated with their kinesthetic memories in the parietal cortex. Then these sensory memories are transferred to the premotor area, which ultimately directs the information to the motor strip, and the action is completed. Ideomotor apraxia can be caused by a lesion anywhere along this circuit. This neural circuit is for apraxia in the right hand. Apraxia in the left hand is regulated by information being transferred from the premotor area on the left to the right premotor area via the corpus callosum. A lesion in this circuit will produce left-hand apraxia, often called sympathetic dyspraxia (Strub and Black, 1993).

Another form of apraxia is buccofacial or oral apraxia. In this type of apraxia, the patient demonstrates an inability to complete skilled movements of the speech apparatus and face. One way to assess for this type of apraxia is to ask the patient to blow out a match or drink from a straw. Verbal or oral-motor apraxia occurs when oral apraxia negatively impacts the ability to produce speech sounds.

There are several types of limb apraxia, which is the inability to perform learned movements with the upper extremities. In limb kinetic apraxia, the patient is unable to make precise individual finger movements. The impairment is typically seen in the hand contralateral to the brain lesion. This may be assessed by asking the patient to pick up a dime from a flat surface. In addition, the Grooved Pegboard Test can be used to help assess this skill (Heilman et al., 1998).

Ideomotor apraxia is the most common type of apraxia. Ideomotor apraxia is caused by a disruption in the praxis production system. In this type of apraxia, errors are most frequently seen when the patient attempts to pantomime transitive (using a tool or instrument) acts to command. In patients with this type apraxia, performance usually improves when patients are allowed to imitate the action. The errors here are primarily spatial and temporal errors. Both perseverative errors and sequencing errors are common. Lesions producing this type of apraxia in right-handed people are usually in the left hemisphere and vice versa and may be in

multiple areas including the corpus callosum, basal ganglia, supplemental motor area, and inferior parietal lobe (Strub and Black, 1993).

In conduction apraxia the patient demonstrates more impairment when trying to imitate action than when asked to pantomime the action based on verbal command. This is caused by a disconnection between the input and output praxicons. The exact location of the lesion that produces this type of apraxia is unknown (Heilman et al., 1998).

In dissociation apraxia, the use of objects themselves and imitation of actions is intact, but the patient is impaired when asked to pantomime an action. Disruption of information passing through the corpus callosum is likely responsible for the production of this type of apraxia. Right-handed patients may demonstrate a combination of dissociation apraxia and ideomotor apraxia following callosal lesions. Left-handed patients may demonstrate ideomotor apraxia without aphasia following right hemisphere lesions (Heilman et al., 1998).

Ideational apraxia results in the patient being unable to formulate an ideational plan for carrying out a series of steps involved in an action. Impairments are noted in the ability to sequence the actions in the proper order. This type of apraxia is caused by difficulty in complex motor planning that is of a higher-order nature than that involved with ideomotor apraxia. Each step of the sequence can be performed in isolation but the person cannot grasp the overall concept and is unable to integrate the parts into complete sequences. The examiner can assess this type apraxia by asking patient to complete a series of actions such as opening a tube of toothpaste, taking a toothbrush from the holder, and placing toothpaste on the toothbrush.

Constructional apraxia occurs when the patient has impairment in the conceptual knowledge needed to select and use objects and tools. The patient demonstrates an inability to recall the types of actions for specific objects and tools. The person with constructional apraxia may have impaired mechanical knowledge, may be unable to describe the function of tools, and/or may be unable to recall which tool goes with which object. These type representations are usually lateralized contralateral to the preferred hand in the temporoparietal junction.

As indicated above, there are several specific tasks that can be used to assess apraxia. One type of assessment task is asking the patient to gesture to command. It is important to include both transitive (using a tool and instrument) and intransitive (communicating gestures) conditions when requesting the patient complete the gesture to command. Another type is gesture imitation. In gesture imitation tasks, the patient should also be asked to gesture in response to seeing and holding tools and objects. Pantomime recognition and discrimination is another type of assessment task. Also, asking the patient to complete sequential acts, such as making a sandwich. In addition, the patient can be asked to demonstrate the association tool-object knowledge and mechanical knowledge.

Stroke patients often are not aware of their apraxic deficits and attribute these problems to inexperience using their left arm or right hemiparesis. Activities of daily living are often impaired in the presence of ideational, ideomotor, and conceptual apraxia. Spontaneous recovery from apraxia for right-handed patients may be due to the right hemisphere ability to develop skilled motor movement support. Surprisingly, despite the prevalence of apraxia in rehabilitation settings, little has been written about systematic efforts for the treatment of limb apraxias. For the most part, reports have consisted of case-series designs (e.g., Smania, Girardi, Domenicali, Loar, and Aglioti, 2000) as opposed to evaluation of actual apraxia treatment strategies (e.g., van Heugten et al., 1998). The results, as a whole, do suggest that

apraxia treatment in stroke patients, in the form of deficit remediation or compensation, can be beneficial in increasing the patient's functional independence (van Heugten et al., 1998). In general, therapeutic efforts target tasks that resemble as closely as possible tasks the patient will face in her/her normal daily routine (Goldenberg, Daumuller, and Hagmann, 2001).

Part of the difficulty in evaluating and treating apraxia, as with many of the disorders listed in this chapter, is that these symptoms often co-exist with other cognitive disorders. For example, a patient recently presented with a left hemisphere stroke that resulted in right hemiparesis and moderate deficits in naming, comprehension, fluency, and repetition (and other cognitive difficulties). She had obvious difficulties in planning motor activities, but the treatment team was not fully able to ascribe the extent of these difficulties to praxis versus language deficits. The patient returned to the rehabilitation unit three months later for deconditioning after pneumonia. At that point she had minor difficulties in naming as the only visible cognitive residual of the stroke, yet it was much easier to see the extent of her apraxia: when she attempted to brush her teeth, after looking confused for several seconds, she raised the toothpaste tube to her lips as if it was a toothbrush.

NEGLECT

Unilateral neglect is often conceptualized as a failure to report, attend to, orient toward, or respond to stimuli presented in a contralateral side of space that cannot be explained by sensory or motor dysfunction (Heilman and Valenstein, 2003). Neglect is probably one of the more frequently encountered conditions listed in this chapter, but one of the least understood. Often missed, particularly in its subtlest forms, or confused with other sensory deficits (e.g., a visual field cut), neglect can be a source of tremendous disability in daily life and a significant challenge to the rehabilitation team. While often simplified to merely a "visual" or "attentional" phenomenon, neglect is actually a multi-faceted disturbance of attention, perception, and/or action (Buxbaum et al., 2004).

Neglect is typically thought of as a non-dominant hemisphere phenomena, meaning that in the majority of individuals this syndrome involves the lack of attention to the left side of hemispace. Right-sided neglect also occurs, although traditional wisdom suggests decreased severity and faster recovery when compared to left-sided neglect. Still, some studies have posited that right-sided neglect occurs, in one form or another, in up to 40% of individuals who have suffered a stroke in their left hemisphere (Beis et al., 2004), indicating that evaluation of these functions regardless of stroke location should take place. Similar to aphasia, various brain structures and regions can be affected and subsequently produce neglect. While the region most often associated with neglect is the right parietal lobe, damage to the thalamus, basal ganglia, and frontal lobe can also produce neglect (Pierce and Buxbaum, 2002).

Neglect, like aphasia, is not a unitary syndrome. Variations can be seen in the severity and type of neglect. In its mildest form, neglect can be seen in extinction of sensation on the affected side when undergoing bilateral sensory stimulation (e.g., the patient will only report feeling right sided stimulation when both hands were touched). As such, the patient may not appear to the treatment team to have any deficits until they are challenged, such as placed in a busy atmosphere with multiple competing stimuli, whereby the manifestations of neglect may

be seen. In more moderate cases of neglect, the inattention to contralateral space becomes quite obvious to observers. It has been well established that the presence of neglect corresponds to poorer rehabilitation outcome than if neglect was not present (Buxbaum et al., 2004). Potential progress in rehabilitation can thus be gauged early on in the inpatient stay by engaging the patient in tasks of orientation to the ignored hemispace and judging how much external cuing it takes to draw the patient's attention to the target. Those who need minimal cuing obviously have a better prognosis for a shorter stay and more functional recovery than those who will never orient far enough to perceive the target stimuli. Perhaps the most severe cases of neglect are in individuals who not only have a severe neglect but also have frank anosognosia regarding their deficit (or, in some cases fail to recognize their contralesional extremities as their own). While some degree of unawareness of deficit occurs in up to 50% of patients with neglect (Gianella and Mattioli, 1992), such gross disregard (often accompanied by confabulation) of deficits is usually associated with large lesions and significant hemiparesis (Leibovitch et al., 1998). In a practical sense, it is fortunate that such individuals are relatively immobile, as otherwise they would certainly cause harm to themselves due to their decreased motor abilities and concomitant unawareness of deficits. Still, such individuals require close supervision, particularly as their motor deficits start to resolve. As motor recovery ensues, neglect also tends to diminish, again suggesting the prognostic value of early identification and assessment of neglect syndromes (Farne et al., 2004). Still, in two patients with similar levels of stroke severity, the one with neglect will likely have an overall poorer functional outcome (Buxbaum et al., 2004; Katz, Hartmann-Maeir, Ring, and Soroker, 1999).

Current thinking conceptualizes neglect as having numerous distinct subtypes. Deficits can be seen in the direction of attention to space that is within reaching distance of the individual or in failure to attend to extrapersonal space that falls outside of one's reach. Perhaps the most recognized deficit applies to personal neglect, whereby the individual fails to groom or dress one side of the body. In addition, neglect may take the form of failure to initiate or respond motorically in the affected hemispace, which can present similar to akinesia but be limited to one hemispace (Coslett, Bowers, and Heilman, 1987). Not surprisingly, the above authors have linked this variant of neglect to lesions of the frontal lobe, while more perceptual neglect tends to occur with more posterior damage, although controversy exists regarding the ability to localize subtypes of neglect to unique regions (Buxbaum et al., 2004). Lastly, the idea or "representation" of space may be lost, in that the individual may not be able to conceptualize of the affected hemispace. We are often able to replicate the classic paradigm first described by Bisiach and Luzzatti (1978) whereby patients have not been able to fully describe a common scene (e.g., facing the town square or city hall) as they neglect the affected hemispace but will correctly report such details (and omit their previous description) when asked to imagine that they are facing the other direction. Thus, it is not surprising that no unifying theory of neglect has emerged, given that visuospatial, sensory, motor, memory, and other "higher order" systems have been implicated in this deficit.

Such knowledge of the heterogeneity of the syndrome also guides the assessment of neglect. While seemingly one of the least quantifiable neurobehavioral syndromes, a variety of instruments have been created to test various for aspects of neglect (for an excellent review see Menon and Korner-Bitensky, 2004). In addition, this process is also conducted at the bedside with numerous nonstandardized instruments. Regardless, many instruments share

common components such as line bisection, cancellation of letters or shapes, free-hand drawings (e.g., clocks, flowers, houses, etc.) and copying of figures, or reading (e.g., the Indented Paragraph Test; Caplan, 1987). Additionally, tasks of mental imagery such as the one previously mentioned, tests of attention to body and extrapersonal space, geographical orientation, and observation in naturalistic settings all can yield clues in the diagnosis of neglect. Heilman, Watson, and Valenstein (1995) propose that testing for sensory inattention and extinction is done across three modalities: somesthetic, visual, and auditory. Testing for motor neglect includes observation in naturalistic settings, having the patient look both toward and away from ipsi- and contralateral stimuli (which, in our experience, is difficult due to many patient's instinct to move their head and/or trunk in relation to the stimulus), and having them identify (with their eyes closed) the midline of their body and of their immediate space. Perhaps the most popular method of testing consists of line bisection, cancellation tasks, and having the patient engage in spontaneous drawings to observe not only for neglect in the reproduced images but also in terms of placement on the page. All written tasks must be presented at the patient's midline and care must be taken to observe the patient's head and trunk movements to make sure that they are not trying to compensate for their neglect (although this is valuable information in its own right). Not surprisingly, given the heterogeneous nature of neglect, it has been suggested that a multimodal approach is necessary, as there is not a single test that is sensitive enough to capture all aspects of neglect (Maeshima et al., 2001).

Hence, it follows that numerous methods of treatment have been proposed. It has long been observed that right-sided strokes often carry with them the sequelae of decreased arousal. Thus, attempts have been made both pharmacologically (e.g., stimulants, dopamine agonists such as bromocriptine, etc.) and psychologically (teaching patients to self-alert) to improve arousal. While preliminary, some positive results have been described, although not consistently (for an excellent review of this and other treatments see Pierce and Buxbaum, 2002). Early attempts at improving visual scanning have shown short-term results but need both replication and proven ability to show generalizing results (e.g., Robertson, Gray, Pentland, and Waite, 1990). Modalities such as eye patching, prism glasses, and mental imagery training have also been reported to have some success, although, again, the literature is scant and in need of further replication (Pierce and Buxbaum, 2002). Perhaps one of the most interesting current lines of research has to do with hemispheric activation theories that propose that even small movements of the affected hand in the affected hemispace can result in decreased neglect. Such theories posit that such actions work to "reactivate" or recruit overlapping neural systems that are involved in the representation of hemispace (Robertson and North, 1993). Efforts have also begun to utilize a similar paradigm of motor activation for the recovery of language abilities after stroke (Raymer, Rowland, Haley, and Crosson, 2002). In addition, if such techniques prove worthwhile, they may be integrated into and complimented by the constraint-induced movement therapy techniques previously discussed (Taub and Wolf, 1997).

PERCEPTUAL DISORDERS

It is well recognized that visual and perceptual disorders can commonly occur after strokes. That being said, it is not unusual for these disorders to be missed in patients who have not undergone a neuropsychological examination. Unlike aphasia or neglect, whose presence is often glaringly obvious, visual-perceptual disorders, short of significant visual field cuts or frank neglect, can be quite subtle in terms of their expression. Their impact on outcome after stroke, however, is well established, especially in limiting the performance of activities of daily living (ADLs; Rubio, and Van Deusen, 1995; Titus, Gall, Yerxa, Roberson, and Mack, 1991). In fact, one of the most recognized ADL disorders, dressing apraxia, is being conceptualized as a sequelae of disturbed visuospatial abilities instead of an apraxia (Fitzgerald, McKelvey, and Szeligo, 2002). Some studies have shown that perceptual disorders have a greater impact than cognitive (e.g., language, memory, problem solving, etc.) difficulties on the level of disability seen acutely after stroke (Mercier, Audet, Hébert, Rochette, and Dubois, 2001). Thus, while often not the easiest of phenomena to explain to stroke patients and their families, perceptual disorders certainly need to be assessed and treated after stroke.

Perception often implies the creation of mental images in secondary and tertiary association cortices after initial processing in the visual cortex. The concept of a ventral (“what”) and a dorsal (“where”) stream comprising the outputs of visual cortex is well known (Mishkin, Ungerleider, and Macko 2000). Benton and Tranel (1993) conceptualized damage to these routes as contributing to three types of disorders: visuoperceptual, visuospatial, and visuoconstructive. Visuoperceptual disorders suggest impairments in processing forms, patterns, colors, shapes, and other features and could lead to visual object agnosia, prosopagnosia (defective facial recognition), and difficulties in color recognition. Visuospatial disorders consist of difficulties in localizing objects in space, defective judgments of direction and space, and defective topographical orientation. Deficits in either written drawing or copying of objects/shapes or in manual manipulation of objects to create or match models or figures comprises visuoconstructive deficits. While traditional logic suggests that the incidence of these disorders is closely associated with right or non-language dominant hemisphere damage, individuals with dominant hemisphere lesions also can show difficulties in some of the areas listed above. For example, Varney (2002) suggests that a significant proportion of individuals with reading disorders secondary to dominant hemisphere lesions often had visuoperceptive deficits that hindered them from recognizing letters and letter-like shapes.

Assessment of perceptual disorders follows from the theories posited above. In practice, the presence of hemiparesis, aphasia, neglect, and/or primary visual disturbances (e.g., field cuts) can often make the assessment of perception challenging. Benton, Sivian, Hamsher, Varney, and Spreen (1994) highlight many of the tests from Benton’s lab that have shown efficacy in assessing perceptual disorders, including measures of facial recognition, line orientation, visual form discrimination, and three-dimensional block construction. The Benton Visual Retention Test (Sivan, 1992), the Rey-Osterrieth Complex Figure Test (Rey, 1941), and the Block Design test from the WAIS-III (Wechsler, 1997) are also commonly used. Tests such as the Motor-Free Visual Perception Test (MVPT-III; Colarusso and Hammill, 2003) may also be utilized when hemiparesis or motor discoordination is present. As

previously stated, measures of perceptual abilities have been shown to be predictive of outcome after stroke rehabilitation and of post-discharge skills such as driving (Korner-Bitensky et al., 2000).

MEMORY DISORDERS

Perhaps the most frequent cognitive complaint that a rehabilitation neuropsychologist will hear from a stroke patient is that of reduced memory abilities. Formal testing may or may not find an actual memory disorder, per se, but rather difficulties in naming, attention, concentration, or organization of storage and/or recall as the cause for what is perceived as a memory difficulty. Still, in our experience, it is rare for a person to complain of difficulties in the components that underlie effective memory functioning, but rather notice the end result of poor retrieval from memory.

Much of our knowledge of memory functioning results from studies of classic cases of diseases that affect mesial temporal and diencephalic structures (e.g., Korsakoff's, herpes encephalitis, etc). Given that these conditions often affect these areas bilaterally, little has been written about strokes and these types of memory disorders simply because of the relative rarity of having two circumscribed strokes. Rather, the literature on stroke has primarily contributed to our understanding of memory disorders through the examination of frontal and thalamic systems.

Perhaps the most recognized amnesic disorder associated with the frontal lobes is the "ACoA syndrome" associated with anterior communicating artery aneurysm ruptures. This proposed syndrome features personality change (decreased awareness, disinhibition, etc.), impaired executive functioning, confabulation, and dense amnesia (DeLuca and Diamond, 1995). While other cognitive functions (i.e., visual-spatial, concentration, etc.), can be relatively spared, these individuals will show marked deficits in verbal recall of information (DeLuca, 1992). In addition, while impaired retrieval from memory is a hallmark of this disorder, some research suggests that impaired acquisition may be more affected than recall in a subgroup of patients with ruptured ACoA aneurysms (Diamond, Deluca, and Kelley, 1997).

The thalamus is one of the few subcortical structures that has received extensive investigation for its role in memory after stroke. Reports of verbal and visual-spatial memory deficits after thalamic infarcts, either in the dominant or non-dominant hemisphere, are plentiful in the literature (e.g., Kopelman et al., 2001). If such lesions are bilateral, frank amnesia is often seen and can be long lasting. It is not uncommon in such cases to see severe deficits in both recall and recognition of newly learned material along with some degree of retrograde amnesia (Isaac et al., 1998; Gentilini, DeRenzi, and Crisi, 1987). Interestingly, while the basal ganglia has been extensively researched in terms of its role in memory disorders with Parkinson's and Huntington's patients, little work has been forthcoming from the literature as to deficits following stroke (Crosson, 1992).

While strokes to the specific areas listed above can cause frank amnesic syndromes, the amount of general cognitive disorganization which accompanies most strokes cannot be underestimated and is often expressed through reduced memory. For example, Mast et al. (1999) found that approximately 35% of their older rehabilitation population that had experienced a stroke met criteria for dementia. Similarly, Ruchinskas, Repetz, and Singer

(2001) found that 70% of their older stroke population scored below a suggested cutting score for dementia on a cognitive screening instrument. What must be noted of all of this research, however, is that patients, even with severe memory disorders, can make functional or physical gains in rehabilitation. Many reasons for this phenomena have been suggested, but perhaps the most cogent explanation is that the areas that neuropsychologists traditionally focus on during their assessment (e.g., verbal and visual memory, attention, etc.) may not play as important an aspect in the physical rehabilitation arena as do other areas of cognition. For example, studies have hypothesized, suggested, and confirmed that procedural memory is dissociable from declarative memory and plays an integral part in the rehabilitation process (Ruchinskias et al., 2000; Patrick, Leber, and Johnston, 1996; Ewert, Levin, Watson, and Kalisky, 1989). This suggests that the neuropsychologist in the rehabilitation setting should incorporate a measure of procedural memory (such as the Rivermead Behavioral Memory Test; Wilson, Cockburn, and Baddeley, 1985), even at the bedside, in the initial evaluation, lest the treatment team become too concerned that the patient cannot verbalize recalling their exercises (yet can learn and perform them from day to day!).

EXECUTIVE FUNCTIONING

Executive functioning refers to a person's ability to plan, initiate, sequence, and monitor behavior that is complex and goal directed (Royall et al., 2002). Executive functioning includes the ability to formulate goals and recognize the long-term consequences of the action being considered. In addition, this area of functioning includes the ability to generate multiple alternative responses to a situation, choose between behavioral alternatives, self-monitor to determine if the behavior taken is accurate, and self-correct the behavioral response as needed. Additionally, the ability to focus and persist in the face of distraction, without becoming so focused that one loses the ability to determine the salience of new information, is a hallmark feature of the executive functions (Malloy, Cohen, and Jenkins, 1998). These functions are necessary for the individual to survive and thrive when managing his/her responses to the internal and external environment and are crucial for determining and engaging in socially appropriate behavior.

While executive functions have traditionally been seen as residing in the frontal lobes, one cannot downplay the numerous frontal-cortical and frontal-subcortical connections that also contribute to these skills. Cummings (1993) provides an excellent discussion of the frontal-subcortical circuits that are thought to form the substrate of the executive functions. Frontally based deficits fall in three realms. The traditional "executive deficits" (e.g., decreased abstraction, reasoning, and awareness) are typically associated with lesions in the dorsolateral prefrontal circuit. Deficits involving disinhibition are typically associated with lesions in the orbitofrontal circuit. Apathy is typically associated with lesions in the anterior cingulate circuit.

Damage to these underlying substrates and circuits leads to impairments in different areas of executive functioning. The executive function syndrome, involving damage to the dorsolateral prefrontal circuit, is characterized by deficits in initiating, planning, monitoring, and maintaining flexible behavior. Patients with this type deficit have problems integrating elements into a whole. In addition, behavioral responding is often characterized by a limited

response set with loss of set and/or perseveration. The disinhibition syndrome, arising from damage to the orbitofrontal circuit, is characterized by disinhibited social behavior. Personality change, poor inhibition, impulsivity and social inappropriateness are characteristic features. Confabulation and emotional lability are also often seen. There is often a significant change in affect with both insight and judgment impaired. The apathetic syndrome, due to lesions in the anterior cingulate circuit, is characterized by failure to respond to environmental stimulation. General apathy in spontaneous actions and motivation is characteristic (Malloy et al., 1998).

Vataja et al. (2003) discusses the MRI correlates of executive dysfunction specifically in stroke patients. In their sample of stroke patients, 34% exhibited problems with executive function. The patients with executive dysfunction had a greater frequency of brain infarctions overall and in the left hemisphere. In addition to this finding, lesions in frontal-subcortical circuits were more common in patients with deficits in executive function. Some patients with pontine lesions also demonstrated executive dysfunction, but this and similar studies' findings may have been due to more extensive ischemic changes in these patients overall (Ruchinskas, 1998). The conclusion from this neuroradiological study was that brain infarcts and lesions of the white matter, which affect frontal-subcortical circuits, create an increased risk for the development of deficits of executive functioning in stroke patients.

While the idea of unawareness of deficits after stroke is well recognized, the decreased recognition of limitations is by no means solely restricted to this population. In fact, the difficulties of correctly defining what is "organically" based unawareness versus "psychologically" based denial are encountered on a daily basis in a rehabilitation setting. Perhaps the most accommodating viewpoint sees awareness as a continuum from frank denial and unawareness to that of almost neurotically based over-focus on perceived deficits that can occur in those with and without neurological disease. While too large to cover in this work, the reader is encouraged to consult Prigatano and Schacter (1991) and Prigatano's subsequent works for a coherent review of this subject. That said, we will briefly review unawareness syndromes that accompany stroke. Historically, it was thought that psychological denial was responsible for much lack of awareness following neurological injury. We now understand that anosognosia, or lack of awareness due to cortical damage, plays a major role in the development of lack of awareness in patients with neurological injury including stroke. The term "anosognosia" was coined by Babinski in 1914 and is considered to be an impairment in executive functioning (Hibbard, Gordon, and Stein, 1992). Traditionally, unawareness of deficit has been believed to be more common following damage to the right hemisphere, especially following basal ganglia and parietal damage, but aspects of unawareness can be seen following damage to the left hemisphere or most any cortical area (Prigatano and Schacter, 1991).

Primary to the belief of decreased awareness after stroke is that patients would consistently overestimate their physical and mental abilities and that this phenomena would occur more often in individuals with right hemisphere strokes. This hypothesis has not been consistently supported. For example, Hibbard et al. (1992) found that the majority of patients with both right and left-hemisphere damage were accurate in rating the extent of the physical impairments they experienced following stroke, although both groups demonstrated an overall lack of accuracy when rating the mood, language, and cognitive changes resulting from stroke. In contrast, two recent studies found that stroke patients rated themselves as less impaired in motor abilities than they were rated by rehabilitation staff although they rated

themselves as more impaired in cognitive and emotional aspects than staff rated them. (Fisher, Trexler, and Gauggel 2004; Gauggel, Peleska, and Bode, 2000).

Regardless, measures of executive function have shown a relationship with ultimate rehabilitation outcome. Tests of executive functioning have been shown to be predictive of ultimate ADL and instrumental ADL abilities (Cahn-Weiner, Boyle, and Malloy, 2002; LaBuda and Lichtenberg, 1999). Thus, it can be hypothesized that high-level cognitive functions are necessary for ultimate rehabilitation success once the patient's sensory and physical impairments have resolved. An alternative possibility is that high-level cognitive functions allow the patient to compensate for unresolved impairments in the other domains. At any rate, while inpatient rehabilitation places a high priority on physical and motor functioning, the assessment and treatment of executive functions cannot be downplayed in respect to the ultimate success or failure in rehabilitation (Hanks, Rapport, Millis, and Deshpande, 1999).

There are several strategies that can be implemented in the assessment of the executive functions. The reader is encouraged to consult Royall et al. (2002) for an excellent review of the overall concepts of executive functioning, the specific executive control circuits and systems, and assessment of executive functions using both bedside and more formal neuropsychological measures. Included in that discussion are the Behavioral Dyscontrol Scale, the Executive Interview, the executive clock drawing task, and the Frontal Assessment Battery.

Malloy et al. (1998) also provide a very nice review of specific assessment approaches. They suggest that in the assessment of the primary motor area the neuropsychologist will find it helpful to perform some aspects of a neurological-type exam, such as having the patient squeeze your fingers. In addition, they suggest using the Grip Strength/Hand Dynamometer and Finger Tapping Test when assessing this area. To assess the premotor area, the Purdue Pegboard Test or Grooved Pegboard Test can be helpful. The frontal eye fields can be productively assessed by using visual search tasks. The dorsolateral area can be assessed by using measures of word fluency, figural fluency, and the Wisconsin Card Sorting Test. The orbital and basal areas can be assessed by using a smell identification test, go/no go tasks and/or the Stroop test. For an extensive review of other measures that can be used to assess the various elements of executive functioning in the assessment of post-acute patients, please see Lezak et al. (2004).

Deficits in executive function may be, but are not necessarily, grossly evident during the rehabilitation process. In the highly structured atmosphere of rehabilitation, difficulties in executive functioning may be relatively subtle and easily missed by the treatment team. It is helpful for the neuropsychologist to be attuned to the concepts and impairment possibilities discussed above so that he/she can recognize the presence of these deficits and the potential impact on the patient's ability to achieve maximum recovery following stroke. The neuropsychologist can then work with the patient, patient's family, and other rehabilitation professionals in identifying, understanding, and addressing these issues so the patient is given the best opportunity to achieve the maximum benefit from the rehabilitation program. While the concept of executive functions may be difficult to explain to individuals and families, there are some simple experiments that can be utilized to illuminate this point. For example, we often ask patients to find their way to the hospital cafeteria, buy an item with the money that we provide, and return within a certain time period (usually with a staff member accompanying but not aiding them). This seemingly simple everyday task can show deficits

in planning, organization, time sense, and other executive functions that will be glaringly obvious to the patient (sometimes) and to the family. At times, the results of these experiments also surprise staff that believe the patient to be functioning at a high level. It is often necessary to mention the nature of inpatient rehabilitation as one of a highly structured existence. Taking away external structure and forcing the patient to use their internal mechanisms often reveals weakness in executive functions and can be a guide as to how much supervision will be necessary upon discharge. Improvements in ADLs can be gained by targeting executive functioning during the rehabilitation process (Honda, 1999). Such strategies usually focus on remediation of deficits or the use of external compensation strategies and devices (i.e., pagers, notebooks, etc.), which are often times the most efficacious approaches when difficulties in awareness or monitoring are present. The reader is encouraged to consult sources such as Sohlberg and Mateer (2001) for a comprehensive approach to remediating executive dysfunction.

CONCLUSION: PRACTICAL ASPECTS OF NEUROPSYCHOLOGY IN STROKE REHABILITATION

The practice of neuropsychology in an acute or post-acute stroke rehabilitation environment is a challenging yet rewarding venture. In acute settings, the practice involves equal parts behavioral neurology and neuropsychology in that the first aspect of the neuropsychological evaluation involves determining the neurobehavioral syndromes that are present that can affect formal neuropsychological assessment. Included in this process is an evaluation of the nature and degree of hemiparesis, ataxia, and motor incoordination. Sensory systems such as vision, audition, and cutaneous sensation must be assessed. Comprehension must be assured, and the ability to express oneself across many mediums must be evaluated. Upon completion of this initial evaluation, the clinician should have a good understanding of the degree of motor weakness/incoordination, sensory deficits (e.g., field cuts, decreased hearing, etc.), aphasia, dysarthria, neglect, etc., that can potentially affect further evaluation (and the rehabilitation process as a whole).

After deciding which cognitive instruments to use, the clinician still faces numerous challenges. Perhaps the most common, yet largely ignored, factor facing the clinician is that of post-stroke fatigue. During the course of the day, an individual is expected to participate in multiple therapies that consume a large portion of their waking hours. During that time, trying to catch an individual while they are “fresh” enough to perform tests that are not always interesting and may challenge areas of cognitive deficit can be a significant challenge. Post-stroke fatigue is quite common (Glader, Stegmayr, and Asplund, 2002) and may also explain some of the performance variability, both in cognitive and physical domains, which is observed by the treatment team. Additionally, there is research that suggests that post-stroke fatigue may not ease during the rehabilitation stay and may, in fact, be quite long-lasting (De Groot, Phillips, and Eskes, 2003). As previously mentioned, difficulties in arousal may also be quite prevalent in (particularly right-sided) strokes, and pose similar problems for assessment and treatment. Lastly, as noted at the beginning of this chapter, the existence of post-stroke depression can negatively impact the evaluation process as well as progress in the

rehabilitation program as a whole in terms of making it difficult for the patient to put forward his best cooperation or effort.

The neuropsychologist working with stroke patients in the rehabilitation setting needs a skill set that is both broad and deep in order to function optimally. The neuropsychologist must be well-versed in neurological syndromes and issues, neurocognitive functioning, neuropsychological assessment, and the assessment and treatment of psychological/emotional issues following stroke. The neuropsychologist in this setting must adopt a focused and practical philosophy of assessment in order to provide the most crucial information to the patient, family, and other team members in a timely fashion. In addition, interventions in this environment to address cognitive and/or emotional issues must be pragmatic and must be undertaken quickly. Besides a large technical knowledge base required to perform successfully as a neuropsychologist in this setting, one must also be attuned to the multiple formal and informal power structures in the rehabilitation environment as well as to the interpersonal and interprofessional relationships within this setting. The neuropsychologist must develop significant diplomacy skills when working with the multiple other treating professionals in this environment. Unlike some practice settings in which the neuropsychologist is the sole provider of services, the neuropsychologist in the rehabilitation setting must be comfortable interacting with multiple other professionals. Blair and Gorman (2003) offer several "survival tips" to assist the neuropsychologist in understanding the social complexities of the rehabilitation setting, adapting neuropsychology practice to this setting, and making the optimal adjustment to this clinical milieu. The neuropsychologist who learns to function effectively in this setting has much to offer the patients, families, and other clinicians and indeed makes a unique and valuable contribution to the rehabilitation and healing of patients following stroke.

Chapter 46

**EFFECTS OF WALKING SPEEDS
AND NORMALIZATION METHODS
ON THE MUSCULAR ACTIVITY OF THE PARETIC
LOWER LIMB IN STROKE SUBJECTS**

ABSTRACT

The purpose of this chapter was to compare the magnitude of the electromyographic (EMG) signals of the paretic lower limb muscles of stroke subjects between comfortable and maximal walking speeds, considering two methods of normalization. A convenience sample of 10 chronic stroke subjects walked at their self-selected comfortable and maximal walking speeds. The EMG signals were collected from the rectus femoris, biceps femoris, tibialis anterior, and lateral gastrocnemius muscles of the paretic lower limb and were quantified by the root mean squares and normalized by the mean and peak dynamic methods. For all muscles, the ANOVA performed on the mean EMG values over specific periods of muscular activity revealed significant interactions between walking speeds and methods of normalization ($9.02 < F < 31.24$; $0.001 < p < 0.016$). The effects of the methods were greatest at the maximal speeds. The inter-subject variability was also modified by the normalization method, but not consistently for all of the muscles, except for the rectus femoris. In general, the greatest inter-subject variability

¹ Address Correspondence and Request for Reprints, Professor Luci Fuscaldi Teixeira-Salmela, Department of Physical Therapy, Universidade Federal de Minas Gerais, Avenida Antônio Carlos, 6627 - Campus Pampulha, 31270-901 Belo Horizonte, Minas Gerais, Brazil, Phone : 55-31-3409-7403; Fax : 55-31-3409-4783 , E-mail: lfts@ufmg.br.

was observed at maximal walking speeds. The normalization methods and the walking speeds modified the EMG levels and the inter-subject variability. These findings should be considered when the impact of locomotor interventions on EMG values with stroke subjects is studied.

Keywords: Electromyography, stroke, gait analysis, walking speed.

INTRODUCTION

Stroke is one of the most common causes of long-term disability worldwide, and is an important public health concern (Geyh *et al.*, 2004). Among all disabilities demonstrated by stroke subjects, impaired walking is considered to be one of the most important (Geyh *et al.*, 2004; Olney and Richards, 1996). It is well recognized that changes in gait performance are the greatest contributors to functional disabilities post-stroke (Jorgensen *et al.*, 1995). In addition, the degree to which walking is impaired following a stroke relates to the severity of the subjects' lower motor extremity deficiencies (Perry *et al.*, 1995) and to the degree to which community subjects are functionally independent (Wade *et al.*, 1987). Furthermore, walking is the activity which stroke subjects rate as being the most important (Bohannon *et al.*, 1988). Considering these factors, several studies have provided better comprehension of gait disturbances of stroke subjects (Olney and Richards, 1996; Jorgensen *et al.*, 1995; Perry *et al.*, 1995; Wade *et al.*, 1987; Bohannon *et al.*, 1988; Bohannon, 1992; Nadeau *et al.*, 1999; Olney *et al.*, 1994; Salbach *et al.*, 2001; Teixeira-Salmela *et al.*, 2001).

One of the most employed variables to investigate gait performance is walking speed (Olney and Richards, 1996; Bohannon, 1992; Nadeau *et al.*, 1999; Olney *et al.*, 1994; Salbach *et al.*, 2001), given its objectivity (Bohannon, 1992; Salbach *et al.*, 2001) and importance for safe ambulation (Cohen *et al.*, 1987). Another variable often used in investigations regarding gait performance is the electromyographic (EMG) activity of the lower limb muscles (Burden *et al.*, 2003; Hesse *et al.*, 2001; Olney and Richards, 1996; Yang and Winter, 1984), since the most significant impairment for gait performance is the inability to generate voluntary muscle contractions of normal magnitudes and in a coordinated manner (Olney and Richards, 1996). However, there were no studies found which compared EMG activity of the lower limb muscles between comfortable and maximal walking speeds with stroke subjects.

Another important question which has not yet been well addressed is related to the optimal normalization method of the EMG signals to be applied in gait analyses of the paretic lower limb of stroke subjects. Burden *et al.* (2003) compared four different methods of normalization of the EMG signals recorded during gait of healthy subjects, walking on a treadmill at normal speeds. Despite their important results, some questions regarding the normalization still remain. One is related to the best normalization method to analyse the muscular activity of stroke subjects during gait. This is mainly for the muscles of the paretic lower limb, which showed decreased capacity to activate motor units, as well as reduced number of functioning motor units and motor unit firing rates (Carr and Shepherd, 1998; McComas *et al.*, 1973). Unanimous agreement on EMG of the lower limb of stroke subjects is the high levels of inter-individual variability (Den Otter *et al.*, 2007; Olney and Richards,

1996). One way of addressing this problem is the investigation of the normalization methods most suitable for the reduction of variability associated with other factors in gait patterns. Amongst the four methods of normalization which have been most investigated, two have been shown to reduce inter-individual variability: The mean and the peak dynamic methods (Burden *et al.*, 2003; Yang and Winter, 1984). Both methods have some advantages, since the normalized values are derived from walking trials (Yang and Winter, 1984).

The first aim of this chapter was to compare the magnitudes of the EMG signals of the paretic lower limb muscles of stroke subjects between comfortable and maximal walking speeds, considering two means of normalization, the mean and peak dynamic methods. The second was to describe the intra- and inter-subject variability of each method at both walking speeds. All comparisons were carried-out considering four different muscles of the paretic lower limb: The rectus femoris, lateral hamstrings (biceps femoris), tibialis anterior, and lateral gastrocnemius. At a given speed, for each muscle, the period of the gait cycle which showed the most important EMG levels, determined from the averaged EMG profiles, were considered for analyses.

METHODS

Subjects

Subjects with hemiparesis due to stroke were recruited from a rehabilitation center in the Montréal area (Institut de réadaptation Gingras-Lindsay-de-Montréal). Participants required the following criteria to participate: 1) had a chronic (six months or more) unilateral stroke, 2) were able to walk 10 meters independently with or without a cane, and 3) had residual weaknesses of the paretic lower limb. The following exclusion criteria were applied: 1) use of orthoses, 2) comprehensive aphasia, 3) incontinence, 4) unstable medical conditions, 5) histories of injuries, and 6) anesthesia of the lower limbs. This information was gathered on a clinical chart, from the participants themselves, or by their proxy. Authorization by the primary care physician was obtained, if necessary. All potential participants completed an informed and written consent prior to the assessment sessions in accordance with the ethical standards of the University ethical committee.

EVALUATION

Clinical Evaluations

For characterization purposes, demographic and clinical data were collected on all subjects by a trained physical therapist. Clinical data were related to the physical impairments of the lower limb evaluated by the lower extremity component (leg and foot) of the Chedoke-McMaster Stroke Assessment (Gowland *et al.*, 1993), balance (Berg Balance Scale) (Berg *et al.*, 1995), and by clinical measures of comfortable and maximal walking speeds, quantified by the five meter walking test (Salbach *et al.*, 2001).

Gait Evaluations

Gait parameters were collected during the five gait cycles at both self-selected comfortable and maximal speeds. Unilateral surface EMG signals of the following four selected muscles of the paretic lower limb were recorded during gait: The rectus femoris, biceps femoris, tibialis anterior, and lateral gastrocnemius. These muscles are recognized as the most important during gait (Olney and Richards, 1996; Winter, 1991) in studies with stroke subjects (Den Otter *et al.*, 2007; Engardt *et al.*, 1995).

Small, disposable, disc silver–silver chloride (Ag/AgCl) surface electrodes with a 13.2 mm² active surface area (AMBU_ Blue Sensor M), were arranged in a bipolar configuration with a two cm inter-electrode distance, and directly applied over the muscle bellies, parallel to their fiber orientation. A reference electrode was placed over the head of the fibula. Each electrode placement site was prepared using recommended preparation techniques (Cram *et al.*, 1998). The EMG cables were connected to a Noraxon Telemetry 900 portable integrated EMG multi-channel transmitter (Noraxon, Scottsdale, AZ) (weight=0.453 kg per transmitter), which was attached around the subjects' waist. All myoelectric signals underwent an analog-digital conversion before being relayed to the receiver/amplifier units. At this point, the myoelectrical signals were amplified with an overall gain of 2,000 and band-pass filtered (10–500 Hz). Finally, the signals were digitized at a sampling frequency of 1,200 Hz and stored on a computer using a custom-made Labview program (National Instruments, Austin, TX).

Electromyographic Data Processing

First, the EMG signals of all the collected gait trials were full wave rectified and band-pass filtered. All raw EMG signals were visually inspected following signal offset removal. Then, the stride characteristics of each gait cycle were determined considering the peak signals provided by the footswitches located on the soles of the shoes at the heel, metatarsal heads, and mid-foot. The EMG data were then, time normalized to 100% of the gait cycle using a two-point method. The EMG and the footswitch signals were processed by a locally developed software.

Out of five collected gait trials, the three which showed the most similar values for speed, cadence, and EMG activity were averaged and selected for analyses. The normalization process of the EMG signals was performed using the mean and the peak dynamic methods. For the mean dynamic method, the mean RMS values for the complete stride of the averaged trials were calculated for each participant. For the peak dynamic method, the maximal RMS values were calculated. To allow comparisons between the magnitudes of muscular activity at the comfortable and maximal walking speeds, the EMG signals at both speeds were normalized using the mean and peak values of the comfortable walking speed.

Finally, for each method and speed, the periods of the gait cycle where the EMG activity was the most important were visually identified for each muscle by careful observations and analyses of the EMG profiles (Figures 1 and 2), considering the specific phases of the gait cycle, as performed in previous studies (Den Otter *et al.*, 2004; Murray *et al.*, 1984; Shiavi *et al.*, 1987; Winter, 1991).

Over each of the selected periods, the means of the EMG values obtained by each normalization method was calculated. Then, the ratio of the differences between the mean

values of the two methods over the peak dynamic method, were calculated to better understand the amplitude differences between these normalization methods. The same approach was used to assess the differences between gait speeds for a given normalization method.

Statistical Analyses

Descriptive statistics (means and standard deviations) were computed for all demographic, clinical, and EMG variables and tests for normality were carried out for all investigated parameters. Two-way repeated measure ANOVAs were employed to investigate the mean and interaction effects between the walking speeds (comfortable and maximal) and the normalization methods (mean and peak).

The coefficients of variation (CV), obtained by the ratio of the standard deviations to the mean values, expressed in percentages (Portney and Watkins, 2000), were used to determine the intra-subject variability for each walking speed, as well as the inter-individual variability for each method of normalization at each walking speed. All statistical analyses were performed with the SPSS® software (version 15.0) with the significance level of $\alpha < 0.05$.

RESULTS

Subjects' Characteristics

Ten hemiparetic subjects, six men and four women, with a mean age of 60 ± 12.4 years (ranging from 46 to 78 years) and a mean time post-stroke of 62.5 ± 52.8 months (ranging from 25 to 172 months), participated. Five subjects were right side paretic. The median Chedoke scores were five and four for the leg and foot, respectively, and the Berg Balance Scale score was 53/56. During the five meter walking test, the mean comfortable walking speed was 0.82 ± 0.29 m/s (ranging from 0.41 to 1.44) and the mean maximal walking speed was 1.22 ± 0.47 m/s (ranging from 0.42 to 2.03). All subjects were able to increase their maximal walking speeds, when compared to the comfortable ones ($p \leq 0.001$).

During EMG data collection, the mean comfortable speed was 0.69 ± 0.30 m/s (ranging from 0.36 to 1.39) and the mean maximal walking was 1.19 ± 0.44 m/s (ranging from 0.49 to 1.71). Once again, all subjects were able to increase their maximal walking speeds, when compared to their comfortable ones ($p \leq 0.001$).

Pattern Characteristics of the EMG Activity

As can be observed in Figures 1 and 2, for all muscles, the average pattern characteristics of the EMG activity were similar between the two methods of normalization, although the EMG levels and the inter-subject variability (one standard deviation) were greatest for the data normalized by the mean dynamic method. The following descriptions regarding the EMG profiles of each muscle could thus, be applied to both methods of normalization.

The patterns of the rectus femoris muscle were biphasic at both walking speeds. Considering the mean profiles, the first period of EMG activity during the gait cycle began at mid-swing (~80%) and finished before mid-stance, 20 and 30% for the maximal and comfortable speeds, respectively. The second period of activity was clearer at maximal speeds and varied from the second half of the stance to the initial swing (maximal speed: 35%-60%; comfortable speed: 50-70%). The three periods of EMG activity were selected for analyses: 0-20%, 35-70%, and 80-100% of the gait cycle. During these periods, the maximal values of the normalized EMG activities were observed just prior to the initial contact.

The patterns of the biceps femoris were monophasic at both walking speeds. The period of the gait cycle of major EMG activity began at mid-swing (~75%), continued until the end of the gait cycle, and ended at the terminal stance (~35%). The highest EMG amplitudes were depicted just prior to the initial contact. For this specific muscle, two periods of EMG activity were selected for analyses: 0-35% and 75-100%.

The tibialis anterior showed biphasic patterns at both walking speeds. The first period of EMG activity began at mid-swing (~80%) and continued until mid-stance (~15%). The second period was observed at the terminal stance and continued until the initial swing (comfortable speed: 45-70%; maximal speed: 40-60%). Three periods were then, selected for analyses: 0-15%, 40-70%, and 80-100%. The maximal levels of EMG activity were often observed at the initial contact. It should also be noted that this muscle had the most similar EMG patterns and amplitudes between the walking speeds (Figures 1 and 2).

The lateral gastrocnemius demonstrated distinct patterns at each speed. At the comfortable speed, monophasic patterns of EMG activity were observed from mid-stance (~25%) to the pre-swing (55%).

The highest EMG values were seen in the middle of the terminal stance. At the maximal speed, biphasic patterns were observed: One period began at the terminal swing (~85%) and continued until mid-stance (~20%), and the second period was from around 25% to 55% of stance. Since this period was common for both speeds, it was thus, selected for analyses.

Figure 1. (Continued)

Figure 1. Electromyographic activity (means $\pm$ SD) normalized by the mean dynamic method during one complete gait cycle of the paretic lower limb muscles, both at comfortable and maximal speeds.

Comparisons Between the Comfortable and Maximal Walking Speeds Considering the Methods of Normalization

The magnitudes of the EMG activity at maximal walking speeds were always greater than those at comfortable speeds for both methods of normalization (Figure 3). For the mean method, the ratios provided in Table 1, ranged from 32 to 126%, greater at the maximal speed. Corresponding values for the peak method ranged from 34 to 122%.

For all statistical analyses, the ANOVAs revealed interaction effects between walking speeds and the methods of normalization ($9.02 < F < 31.24$; $0.001 < p < 0.016$), indicating that the normalization method had greater effects on the mean data at the maximal speed with the steepest decreasing slope (Figure 3).

Consequently, for most muscles over the analyzed periods of the gait cycles, the greatest differences between speeds were observed for the data normalized by the mean method (Figure 3).

As given in Table 1, the ratios computed from the mean values reported in Figure 3, revealed that at the comfortable and maximal walking speeds, the values of the mean method of normalization were respectively 64 to 100% and 67 to 103% greater than the values obtained by the peak method.

Table 1. Mean magnitudes of the electromyographic activity ratios (%) between each method of normalization at comfortable and maximal walking speeds and between walking speeds normalized by the peak and mean dynamic methods.

Figure 2. Electromyographic activity (means $\pm$ SD) normalized by the peak dynamic method during one complete gait cycle of the paretic lower limb muscles, both at comfortable and maximal speeds.

Intra- and Inter-Subject Variability of the EMG Signal Amplitudes

Table 2 shows the range of the coefficients of variation related to the intra-subject variability at both walking speeds and normalization methods. For both speeds and methods of normalization, the maximal values were lower than 20%, which indicated that the intra-subject variability was low.

As shown in Figures 1 and 2, differences existed regarding the inter-subject variability of the data obtained by the two normalization methods, with greater standard deviation values

generally associated with the mean method. Observations of the coefficients of variation (Table 3) did not reveal consistent effects of the method on the inter-subject relative variability, except for the rectus femoris, which demonstrated no method effects, since for all analysed gait periods, the coefficient of variation values, obtained by both normalization methods, were lower than 10%.

RF: Rectus femoris; BF: Biceps femoris; TA: Tibialis anterior; LG: Lateral gastrocnemius.

Observations of the standard deviations (Figure 3) and the coefficients of variation (Table 3) showed that for most muscles over the analyzed periods of the gait cycle, the inter-subject variability of the EMG values at maximal speeds was greater than those obtained at comfortable walking speeds, independent of the method of normalization.

DISCUSSION

The overall aim of this chapter was to compare the magnitudes of the EMG signals of the paretic lower limb muscles of stroke subjects walking at comfortable and maximal walking speeds with two forms of normalization, the mean and the peak dynamic methods. The stroke participants had lower comfortable and maximal walking speeds, compared to values reported for healthy subjects. As reported by Shavi *et al.* (1987), able-bodied individuals showed a mean comfortable walking speed of 1.44 and maximum of 1.81 m/s. For the present stroke subjects, corresponding values were 0.69 and 1.19, which represented a mean reduction of 52.1 and 34.5%, respectively. Based upon the classification of walking handicaps in a stroke population by Perry *et al.* (1995), the participants fell within the category of “community-walkers” showing full independence in all home and community activities with low risks of falling. The present findings indicated that the method of normalization and the walking speeds modified the EMG activity on the paretic lower limb muscles. The patterns of the peak and the mean methods were differently affected by the walking speeds, since interactions between the walking speeds and normalization methods were observed for all periods of activities for all analyzed muscles.

Pattern Characteristics of EMG Activity

The patterns of the EMG activity were quite similar between the methods of normalization. The periods of gait cycles selected for analyses, which were related to the most important EMG levels of the averaged profiles, were almost equivalent to those chosen by Winter (1991) as being the most important peak activity levels observed during gait of

healthy subjects. However, some periods of the most relevant EMG levels of the stroke subjects were slightly longer than those described by Winter (1991), probably due to the fact that they walk slower than healthy subjects. As pointed out by den Otter *et al.* (2004), the amplitude of muscular activity increases with walking speed, due to the need for larger muscular force output. This is because the main role of the muscles in the control of walking speed is to accelerate and decelerate forces of body segments to allow safe forward progression (Winter, 1991). However, since visual inspection was used to determine the EMG onsets and offsets, it is possible that the differences could be partially attributed to the subjectivity of the method itself.

Individual analyses of the EMG activity of each muscle showed that for the rectus femoris and tibialis anterior muscles, the biphasic patterns of EMG activity were quite similar to those of healthy subjects at both walking speeds. As Winter (1991) described, for the rectus femoris, a peak of EMG activity was observed from the end to the beginning of the gait cycle, during weight acceptance phase and after the toe-off to pull the swinging limb forward. For the tibialis anterior, a peak in activity at the beginning of the gait cycle was observed, which corresponded to force generation in opposition to the plantar flexor ground reaction forces. A second important peak in the activity of the tibialis anterior was observed at the end of the stance and during the swing phases, which corresponded to the generation of force for foot clearance. In addition, over all of the analyzed muscles, the tibialis anterior showed the most consistent patterns between the comfortable and maximal walking speeds. For the biceps femoris, a peak in the EMG activity was also observed at the end and beginning of the gait cycle to prepare for weight acceptance.

Finally, for the lateral gastrocnemius, the monophasic patterns observed during comfortable walking speeds changed to biphasic ones at maximal speeds. A new period of EMG activity began at the terminal swing and continued until mid-stance. The period which was similar at both walking speeds was observed during the mid- and late-stance, which was related to the active plantar flexion of the foot and the generation of the most important impulses of energy (Winter, 1991). The new burst of EMG activity observed for this muscle from the terminal swing until mid-stance at maximal speeds might be related to the biomechanical demands associated to increases in walking speed (Shiavi *et al.*, 1987) and also to the spasticity of the plantar flexors. The lateral gastrocnemius can act both at the knee and ankle joints and during weight acceptance. The amount of energy absorption at the ankle and knee joints increases at higher walking speeds (Teixeira-Salmela *et al.*, 2008), which could explain the new period of EMG activity observed in this muscle from the terminal swing to mid-stance. In addition, it is important to point out that variance in the EMG signal at maximal speeds also seemed to increase during this period. Considering that this new burst of EMG activity could be related to the biomechanical demands associated with increases in walking speed (Shiavi *et al.*, 1987) and also to the spasticity of the plantar flexors, more motor units need to be recruited. Since the muscles of the paretic lower limb of subjects with stroke demonstrated decreased capacities to activate motor units, as well as reduced numbers of functioning motor units and the motor unit firing rates (Carr and Shepherd, 1998; McComas *et al.*, 1973), greater variability in the EMG signal is observed when more motor units were recruited (Nandedkar, 2002; Grosse *et al.*, 2002).

These results were also, in general, similar to those reported by Shiavi *et al.* (1987), who described the EMG activity pattern characteristics of the lower limb muscles at different walking speeds (free, fast, slow, and very slow) with healthy subjects. The rectus femoris and

tibialis anterior muscles showed biphasic patterns for all speeds, and a second distinct period in EMG activity of the gastrocnemius was developed at fast speeds during the swing-to-stance transition. Furthermore, the tibialis anterior had the most consistent patterns across all walking speeds (Shiavi *et al.*, 1987). The EMG pattern characteristics obtained by the two methods of normalization were similar although the magnitudes of the EMG signals varied.

Despite the similarities in the EMG pattern characteristics between the two methods of normalization, in general, the greatest values in the magnitudes of EMG activity were observed for the data normalized by the mean dynamic method and the inter-subject variability was greater at maximal walking speeds. It is important to point out that the analyzed gait trials demonstrated low intra-subject variability, since all of the coefficient of variation values were lower than 20% (Burden *et al.*, 2003; Portney and Watkins, 2000) at both speeds and normalization methods.

Methods of Normalization

An important issue related to EMG analyses is associated with the method of normalization of the EMG signals (Turker, 1993; Yang and Winter, 1984). The most common employed method is the maximum voluntary isometric contraction (MVIC) (Turker, 1993), however, important limitations are associated with this method. The first one is that the MVIC relies upon a voluntary component, which is even further complicated when the data are collected from subjects with pain and/or muscular coordination problems (Cram *et al.*, 1998), as observed in stroke subjects (Carr and Shepherd, 1998; McComas *et al.*, 1973). Another limitation refers to the values used to normalize the EMG data, which are obtained from a specific situation different from the activity of interest (i.e., gait), besides being time consuming (Cram *et al.*, 1998). Finally, the MVIC method showed the highest values of inter-subject variability in previous studies which compared different methods of normalization of the EMG signals of the lower limb muscles during gait (Burden *et al.*, 2003; Yang and Winter, 1984). As pointed out by Yang and Winter (1984), the normalization of EMG activity of the lower limb muscles during gait, with either the peak or the mean dynamic methods, drastically reduced inter-subject variability and increased the sensitivity of surface EMGs as diagnostic tools for gait analyses.

Considering that the main problem in reporting on EMG activity of lower limb muscles of stroke subjects is the inter-individual variability (Den Otter *et al.*, 2007; Olney and Richards, 1996), only the two methods that have shown the lowest variation values (Burden *et al.*, 2003; Yang and Winter, 1984) were compared.

These methods have also the advantage that the normalized values are derived from walking trials (Yang and Winter, 1984). Based on the observed standard deviation values, the peak method showed the lowest variability for all muscles across all intervals of the analyzed gait cycle. However, analyses of the coefficients of variation, which account for relative differences in the magnitude of the means, revealed that the variability of the data was not homogeneous according to the normalization method.

Except for the rectus femoris which showed similar values, the inter-subject variability of the EMGs on the paretic lower limb at different walking speeds and/or at different intervals of the gait cycle, varied in a non-systematic way with one method which provided lower values

of inter-subject variability than the other. These observations leave future studies uncertain regarding which method to employ and call for other studies.

Similar results were reported by Shiavi *et al.* (1987), who investigated the inter-subject variability of the EMG data of the lower limb muscles of healthy subjects at comfortable walking speeds normalized by the mean and peak dynamic methods. For the rectus femoris, the peak method showed the lowest coefficient of variation values at both gait speeds.

On the other hand, for the gastrocnemius muscles, the mean method showed the lowest variability values at both gait speeds. As previously stated, amongst the four methods of normalization which have been most investigated, the mean and the peak dynamic methods have been shown to provide lower values of inter-individual variability (Burden *et al.*, 2003; Yang and Winter, 1984). Based upon the present results and on those reported by Shiavi *et al.* (1987), when comparisons between the normalization methods were carried out, the peak appeared to be the most appropriate to reduce inter-subject variability of the EMG activity of the rectus femoris, whereas the mean demonstrated to be most appropriate to reduce inter-subject variability of the gastrocnemius muscles during gait, for healthy and stroke subjects, at both comfortable and maximal walking speeds. For the other muscles, it is recommended to perform initial analyses regarding the best method to reduce inter-subject variability.

In agreement with previous studies which compared EMG activities during gait performance of healthy subjects normalized by these two methods, the present results clearly showed that the mean method produced the highest values of EMG activity at both walking speeds. This may be explained by the fact that for this method, lower values were used to normalize the EMG signals compared to the peak method, resulting in the greatest ratio values (Cram *et al.*, 1998).

Interaction Effects Between Walking Speeds and Methods of Normalization

Interactions were found between walking speeds and the methods of normalization for all the assessed gait periods. The differences in EMG activity between comfortable and maximal walking speeds were dependent on the method of normalization.

Therefore, if the aim of a given study is to compare the magnitudes of EMG activity between comfortable and maximal walking speeds, different results would be found depending on the normalization method.

Burden *et al.* (2003) compared four different methods of normalizing EMG signals recorded during the gait of healthy subjects on a treadmill at their normal walking speeds. They also reported similar patterns of muscular activity between the mean and the peak methods.

However, comparisons of the magnitudes of EMG activity were performed only for the isometric and isokinetic maximal voluntary contraction methods of normalization, only in a descriptive manner. The large mean percentage differences between these normalization methods observed by Burden *et al.* (2003) ranged from 21 to 33%.

Since no previous studies were found regarding comparisons of the magnitudes of EMG activity normalized by the employed present methods, it was not possible to conclude that these interactions were only observed for the muscles of the paretic lower limb of stroke subjects.

Therefore, future studies aimed at comparing EMG data during different conditions (walking speeds, pre-post interventions, gait with and without assistive devices) and/or groups, should perform initial analyses of the EMG data considering the various methods of normalization before reporting their main results. This statement must be taken into consideration when the analyses are related to the EMG activity of the paretic lower limb muscles of stroke subjects during gait at maximal speeds. As pointed out, the method of normalization can potentially alter the final results.

EMG Activity at Comfortable and Maximal Walking Speeds

Subjects with a history of stroke are able to increase their walking speeds above their comfortable levels (Bohannon, 1992). The present findings revealed that these subjects were also able to increase the EMG activity of the muscles of the paretic lower limb at maximal walking speeds above the levels observed during comfortable speeds. For all evaluated muscles, the EMG activity was always greater at maximal walking speeds for both methods of normalization.

These findings were similar to those reported by Hesse *et al.* (2001), who investigated the relationships between treadmill speeds and lower limb muscular activity in ambulatory hemiparetic subjects.

They reported positive and significant correlations between these variables (Hesse *et al.*, 2001). Greater walking speeds also increased activation of the paretic lower limb muscles. Similar results were also reported in studies with healthy subjects ((Den Otter *et al.*, 2004; Murray *et al.*, 1984), but the differences in the magnitudes of the EMG activity levels between speeds were considerably lower than those presently found.

Faster walking speeds require greater acceleration and deceleration muscular forces and, thus, are reflected by greater EMG levels. Milot *et al.* (2007) evaluated the paretic lower limb muscles of chronic hemiparetic subjects at comfortable and maximal walking speeds.

They investigated the muscular utilization ratio, an outcome which integrates both muscular strength and gait parameters within the concept of levels of effort, and found that the peak muscular utilization ratios increased with walking speeds.

Besides the greater values of magnitude of the EMG activity at maximal walking speeds, the periods were more clearly determined and the timing periods occurred earlier in the relative stride durations at maximal walking speeds. These results were also supported by Shiavi *et al.* (1987), who described the EMG activity patterns of the lower limb muscles at different walking speeds for healthy subjects.

CONCLUSIONS

Increases in EMG activity with faster walking speeds were associated with more variable patterns of muscular activation. For most muscles and intervals of the analyzed gait cycles, the maximal walking speeds showed the greatest variability values for both methods of normalization.

However, previous studies which compared the EMG activity of the lower limb muscles of healthy subjects at different walking speeds reported that, in general, the variability of the EMG signals decreased as speed increased. In stroke subjects, greater variability in the EMG signals of the paretic lower limb muscles may be associated with the utilization of different muscular strategies to increase speed.

The methods of normalization and the walking speeds modified the magnitudes of EMG activity of the paretic lower limb muscles of stroke subjects and the effects of the methods of normalization were greater at maximal walking speeds. The intra-subject variability was lower for both speeds and normalization methods.

However, the inter-subject variability showed higher values, which were not consistently modified by the method of normalization for the analyzed muscles, except for the rectus femoris. Therefore, it is recommended to perform initial analyses of the EMG data, before choosing the best normalization method to reduce inter-subject variability. These results should be considered when the impacts of locomotor interventions on EMG values with stroke subjects are evaluated.

Chapter 47

CARDIAC SWINGING CALCIFIED AMORPHOUS TUMORS (SCAT) AND STROKE IN END-STAGE RENAL FAILURE

Hiroshi Kubota*

Department of Cardiovascular Surgery,
Kyorin University, Tokyo, Japan

ABSTRACT

Cardiac calcified amorphous tumors (cardiac CATs) are unusual non-neoplastic cardiac masses that were originally described in 1997 by Reynolds et al. We recently encountered two patients with a left ventricular cardiac CAT who were successfully treated surgically. Both patients were on hemodialysis for end-stage renal failure and had mitral annular calcification (MAC). In one patient there was massive cardiac calcification. These tumors were fragile, and easily detached from the endocardium. The histological findings were thrombus with angiogenesis and fibrin and calcium deposition. These tumors might be included a special entity of cardiac CATs and may account for some of the strokes or sudden deaths that occur in end-stage renal failure patients who are on hemodialysis. Through the case presentation and literature review, the characteristics and the etiology of the tumor are discussed. The descriptive term of cardiac *swinging calcified amorphous tumor* (cardiac SCAT) is proposed to describe this special risky subgroup of cardiac CATs.

In the Framingham study, mitral annular calcification (MAC) is predictive of a doubling in the risk of stroke after adjustment for multiple risk factors. However, it is still unknown whether the MAC itself is a factor that directly causes stroke or only a marker of increased risk in association with some other unknown factor.

In this chapter, through two clinical cases and literature review, the essence of the cardiac SCAT is discussed.

CASES

Case 1. A 64 y.o. female was referred to our hospital with a diagnosis of pneumonia. She had been on hemodialysis for five years because of diabetic nephropathy. A chest X-ray showed diffuse consolidation in both lung fields. Computed tomography revealed heavily calcified mitral annulus. The leukocyte count was 12,400/ml, and C-reactive protein was 6.4 mg/ml. A blood culture was negative. An echocardiogram showed moderate aortic and mitral regurgitation, and a pedunculated, crotchet shaped mobile tumor that originated from the annulus of the anterior commissure of the mitral valve. The tumor was visualized as a hyper- and homogeneous echo measuring 3 mm x 27 mm (Figure 1). In the systolic phase, it swung widely and its head plunged through the aortic valve into the ascending aorta. A small low-echoic lesion was seen at the center of the tumor head.

Routine echocardiography two months before did not show any evidence of a tumor in the heart. The preoperative diagnosis was infectious endocarditis and pneumonia, and at that time, the tumor was thought to be a vegetation. Because the tumor grew fast, to prevent stroke or systemic embolism, emergency aortic and mitral valve replacement with mechanical valves and tumor resection was performed. Although both valves showed degenerative change, there was no evidence of infectious endocarditis. A soft, fragile, club-shaped tumor that arose from the anterior mitral commissure was easily removed from its origin with forceps without exerting force. There were no other tumors. The postoperative course was uneventful. The patient recovered from pneumonia. She is alive and well with no evidence of recurrence of the tumor as of three years of follow up.

Case 2. A 44 y. o. male who had been on hemodialysis for nine years because of lupus nephritis consulted a cardiologist because routine echocardiography had revealed a mobile tumor in the left ventricle.

Computed tomography showed a densely calcified left ventricle, mitral annulus, and left atrial wall (Figure 2).

Laboratory data showed no evidence of an inflammatory reaction. The tumor was hyperechoic, measured 5 mm x 18 mm, and originated from the base of the anterior papillary muscle (Figure 3). A small low-echoic lesion was seen at the center of the tumor head.

Because follow-up echocardiography 6 weeks later showed that the tumor had grown to 5 mm x 28 mm, elective surgical treatment was performed.

The inside of the left ventricle was visualized with the cardioscope inserted through the orifice of the mitral valve. Three tumors were detected inside the left ventricle (Figure 4).

The head of the tumor was detected in the left ventricle in the diastolic phase (arrow). The tumor plunged through the aortic valve into the ascending aorta in the systolic phase (arrow).

Figure 1. Transesophageal echocardiography.

A computed tomographic scan showed a densely calcified left ventricle, mitral annulus, and left atrial wall. There was no coronary artery stenosis.

Figure 2. Computed tomography and 3-D computed tomography.

One was a mobile tumor that had been detected preoperatively (A), and the other two were immobile and firmly attached to the left ventricle (B and C). All tumors were resected from their origin. The mobile tumor was fragile and removed from the left ventricular wall without force, whereas the other two tumors were firmly anchored to the tuberculum of the left ventricle, and were resected with scissors. The postoperative course was uneventful. Aortic and mitral valve replacement using mechanical valves was performed because of both stenosis and regurgitation one year after tumor resection. The patient is alive and well with no evidence of the tumor three years after the initial operation.

Echocardiography revealed a mobile swinging pedunculated tumor (arrows) originating from the left ventricle. A small, low echoic area at the center of the tumor head could be detected.

Figure 3.

Tumor “A” was a mobile tumor; only the head portion is shown. Tumor “B” and “C” were immobile and firmly attached to the myocardium.

Figure 4. Thoracoscopic view of the left ventricle.

In case 1, pathological examination revealed that the tumor consisted of fibrin. Calcium deposits were detected around the fibrin, but there was no thrombus or capillary angiogenesis (Figure 5). At the proximal part of the stalk, beside the calcified portion, foreign body giant cells were identified (Figure 6).

In case 2, there was red thrombus and capillary angiogenesis in the center of the head of the mobile tumor, which was compatible with the low-echoic lesion. The red thrombus was covered by fibrin and calcium deposition (Figure 7).

Calcium deposits around the fibrin are seen.

Figure 5. Microscopic appearance of the mobile tumor head in patient 1.

At the proximal part of the stalk, beside the calcified portion, foreign body giant cells were identified.

Figure 6. Microscopic appearance of the mobile tumor stalk in patient 1.

Fibroblasts and capillary angiogenesis are seen in the red thrombus. Fibrin and calcium deposits are seen covering the thrombus.

Figure 7. Microscopic appearance of the mobile tumor head in patient 2.

No thrombus or fibrin was seen. It was characterized by monotonous calcification (= ossification).

Figure 8. Microscopic appearance of the immobile tumor in patient 2.

The two immobile tumors were characterized by monotonous calcification (=ossification) and no any structure, e. g. no thrombus or fibrin (Figure 8).

REVIEW

The cardiac calcified amorphous tumor (cardiac CAT) originally described in 1997 by Reynolds et al. is very rare non-neoplastic cardiac mass, and their etiology, clinical manifestations, and treatment are still unclear [1]. We encountered two cases of cardiac mobile CAT described above. Both two cases were in end-stage renal failure, and required hemodialysis. They also showed severe mitral annular calcification [2]. In the Framingham study, mitral annular calcification (MAC) is predictive of a doubling in the risk of stroke after adjustment for multiple risk factors [3]. However, it is still unknown whether the MAC itself is a factor that directly causes stroke or only a marker of increased risk in association with some other unknown factor. Since the report of a stroke in a patient with MAC by Rytand and Lipstich in 1946 [4], the association between MAC and stroke has been studied by numerous investigators [5-7]. In the Boston Area Anticoagulation Trial for Atrial Fibrillation, MAC was associated with an increased risk of stroke [8]. Postmortem studies have long suggested that MAC may directly cause cerebrovascular accident (CVA) by serving as a source of calcific or thrombotic emboli [9, 10]. Some neuroimaging studies have documented calcific deposits in the cerebral arteries of patients with MAC and CVA [11-13]. In an elderly, longitudinally followed cohort of the Framingham study, Benjamin and coworkers examined the relation between mitral annular calcification and the incidence of stroke in a population-based study [3]. The incidence of stroke during eight years of follow-up was analyzed with a proportional-hazards model adjusting for the mitral annular calcification, age, sex, systolic blood pressure, diabetes mellitus, cigarette smoking, atrial fibrillation, and coronary heart disease or congestive heart failure. As a result, among 1159 subjects whose echocardiograms could be assessed for mitral annular calcification and who had no history or current evidence of stroke at the index examination (51% of all subjects), the prevalence of MAC was 10.3% in the men and 15.8% in the women. Multivariate analysis demonstrated that the presence of MAC was associated with a relative risk of stroke of 2.10 (95% confidence interval, 1.24 to 3.57; $p=0.006$). There was a continuous relation between the incidence of stroke and the severity of MAC; each millimeter of thickening as shown on the echocardiogram represented a relative risk of stroke of 1.24 (95% confidence interval, 1.12 to 1.37; $P<0.001$). Furthermore, even when subjects with coronary heart disease or congestive heart failure were excluded from the analysis, subjects with MAC still had twice the risk of stroke. With these results, they concluded that in an elderly, longitudinally followed population-based cohort, MAC was associated with a doubled risk of stroke, independently of traditional risk factors for stroke. De Bono reported echocardiographic features of extensive MAC in 8 of 151 consecutive patients (5%) with cerebral or retinal ischemic episodes but in none of 188 control patients [14]. Nair et al. followed a cohort of 107 patients with MAC and 107 age- and sex-matched control subjects without MAC were studied and followed for a mean of 4.4 ± 2.4 years. Patients with MAC had higher incidence of cerebrovascular events, occurred in 10% of them as opposed to in 2% in matched control patients [15]. However, it is still unknown whether such calcification contributes directly causally to the risk of stroke or is

merely a marker of increased risk because of its association with other precursors of stroke remains unknown.

Reynolds et al. originally reported 11 cases of cardiac CAT in 1997 [1]. Surgical excision was the treatment of choice in 10 patients. The lesions were firm, yellow-white, and partially calcified, and arose in any of the four chambers. Microscopically, all lesions were similar and composed of nodular deposits or flecks of calcium within a background of eosinophilic, amorphous, sometimes fibrillary material. They hypothesized that it was possible that these masses had been ordinary thrombi that had undergone mummification and calcification rather than organization, at the same time, they posed questions for this hypothesis because none of the tumors showed the characteristic laminations observed in typical organizing thrombi and only three patients had hemosiderin deposition. In this patients series, there was only one patient who had end-stage renal failure as an underlying disease. Although there are no description about tumor mobility or growth speed, only one tumor showed club-shaped (0.3x0.3x1.5 cm) in contrast to the others showed ball shaped. It is noteworthy that this club-shaped tumor was found in a patient who had end-stage renal disease with tumoral calcified left ventricle (the site was undescribed). Pathologically, giant cell was detected only in this patient.

Tsuchihashi et al. reported four cases of rapidly growing mobile cardiac calcinosis accompanied by MAC [16]. One of the patients had right hemiplegia, and another died suddenly after four months of follow up. One patient died of acute myocardial infarction secondary to multivessel disease, and surgical resection was performed in the fourth patient.

A few older postmortem case reports and studies suggested a pathophysiologic link between MAC and stroke. Ulceration of the mitral annulus and extrusion of calcium through the overlapping cusp was observed by Pomerance in 5% of 258 autopsy cases [9], and calcific emboli to the brain and other organs from ulcerated MAC were then reported by Ridolfi and Hutchins [17].

In 1995, Stein and Soble described two patients with cerebral embolism who had mitral valve calcification and a soft mobile mass that appeared to be thrombus on the calcified portion of the mitral apparatus [18], and they confirmed resolution of the masses in both patients after antiplatelet and anticoagulation therapy using Aspirin and Warfarin. They concluded that these cases supported the hypothesis that thrombus formation is a pathophysiological link between ischemic cerebral events and MAC in some patients. They mentioned that whether antiplatelet or anticoagulant therapy might prevent cerebral embolism in patients with MAC is unknown and is worthy for further study.

Willens et al. treated rapidly progressing mobile components associated with MAC in patients with chronic renal failure with the phosphorus lowering agent sevelamer HCL and aspirin and obtained resolution. Eicher et al. focused on the echocardiographic findings and the association between MAC and risk of thromboembolism [19]. Among 182 patients who underwent both transthoracic (TTE) and transesophageal echocardiography (TEE) after an arterial thromboembolic event, they identified 10 patients (5.5%) who had MAC and no any other potential embolic substrate. In 3 of them (1.64%), TEE disclosed a long, pedunculated, vegetation-like mass attached to the posterior part of a heavily calcified fibrotic mitral annulus. All 3 patients were treated by anticoagulation with aspirin or dipyridamole concomitant with fluindione. Since regression and complete resolution were achieved, they proposed that when a mitral annular thrombus is diagnosed, anticoagulation therapy and antithrombotic agents should be given for a synergistic effect. They also suggested

pedunculated thrombi of the mitral annulus are a possible “missing link” between MAC and stroke.

Although some reports try to distinguish thrombi from CATs, the pathological findings in our two cases and the courses of the reported clinical cases described above suggest that, cardiac CAT may be the late phase of chronological changes of thrombus in the early phase. The reason why cardiac CATs originate mainly from MAC is unclear. Considering that MAC occurs in >40% of the patients with end-stage renal disease, as our second case shows, they not only originates from MAC but from everywhere the calcified part of the heart and MAC is only the most popular portion to be calcified [20]. It is not clearly understood why the cardiac base is vulnerable to calcium deposits. In extraskeletal calcinosis, Ca-P deposits on the multifollicular fibrous wall are also seen frequently in the hyperkinetic joint capsule. The similarity of the histological and pathophysiological background of the target tissue may explain the deposit of fibrous tissue in cardiac base. But the clinical significance of cardiac calcinosis is very different from joint calcinosis. Injury and erosion of the endocardium or myocardium caused by calcium deposition and inflammation may be related to the initial development of the CAT. Continuously, with the expose to the bloodstream, thrombi with capillary angiogenesis grow with the fibrin exudation and calcium deposition. Secondary hyperparathyroidism may also plays a key role in the cause of cardiac calcification, where the $\text{Ca} \times \text{P}$ product is <50 [21]. Serum magnesium, vitamin D, and serum aluminum are all influential factors. A further symptom of rapid cardiac calcinosis is hypoparathyroidism. Patients on hemodialysis with hyper parathyroidism had a higher incidence of metastatic calcification, which resulted from the decreased reservoir function of bone for absorbed calcium and phosphate from the intestine [22]. Moreover, generally administered calcium and active vitamin D₃ could exacerbate hypercalcemia, and might increase the risk of tumoral calcinosis in the cardiovascular system of patients with end stage renal disease and hypoparathyroidism. As the calcium deposition progresses over time, the capillary vessels, fibrin, and thrombus may disappear. Abnormal calcium and phosphate metabolism due to chronic renal dysfunction and the inflammatory state associated with hemodialysis may contribute to the endothelial erosion postulated to underline these rapid growth and rapid pathological change [23]. The appearance of the foreign body giant cells may represent the relationship with the immunological and inflammatory reaction. However, we cannot find any reason to explain why there are two types of calcified tumor in even though the same patient as case 2: immobile firmly attached one to the heart or mobile, clubbed shaped, rapid growing and fragile tumor.

The definition of cardiac CAT is still in vague. In the literature, cardiac CATs are described as consisting of a wide spectrum of tumor morphologies and pathological characteristics. A case report described a case of diffuse calcific infiltration of the left ventricular myocardium without mobile component as a cardiac CAT [24]. Other authors reported a right ventricular nonmobile calcified 1.5-cm mass involving the annulus of the tricuspid valve as a cardiac CAT [25]. Massive cardiac calcification, cardiac calcified mass or porcelain heart may be suitable expression to describe such tumorous calcification [26]. Based on the intraoperative findings in our two cases and literature review, mobile CATs that exhibited a swinging motion clearly indicate an impending risk of stroke, myocardial infarction, or other systemic embolism. They may occupy some part of the possible “missing link” between MAC and stroke in hemodialyzed end-stage renal disease patients.

Thus, mobile, swinging cardiac CATs should be regarded as distinct from the porcelain heart or immobile cardiac CAT. We propose the descriptive term of *swinging calcified amorphous tumor* (SCAT) to describe this high risk subgroup of cardiac CAT. SCATs are soft, fragile tumor that easily detach from the endocardium, whereas immobile CATs are firmly anchored to the myocardium. They are usually found in patients who require hemodialysis, and originate from any calcified part of the heart. MAC is known as the main site, however, MAC is not the specific site as their origin. As differential diagnosis, other cardiac masses e.g., myxoma, fibroelastoma, vegetation due to infectious endocarditis, malignant cardiac tumors etc. are listed. Especially, calcified tumors e.g., calcified myocardial tuberculomas, tephaceous pseudogout, and osteosarcoma should be carefully differentiated [27].

The incidence of this special category of intracardiac tumor is unclear. However, in view of fact that two cases were treated in same year at a single institution, awareness of this tumor and routine echocardiographic evaluation of patients with MAC or cardiac calcification who are on hemodialysis may lead to the discovery of more cases. Further serological and pathological investigation will reveal the mechanism of the development, growth, and chronological changes in SCATs. Anticoagulation therapy and antithrombotic agents may affect not only on the outside of the tumor but from inside via capillary vessels. As cases accumulate, proper protocol of treatment will be established.

CONCLUSION

In conclusion, routine follow-up echocardiography is recommended for the patients with MAC or cardiac calcification who are on hemodialysis. Although the efficacy of a preventive anticoagulant is a matter of controversy, immediate anticoagulation, anti-inflammation and thrombolytic therapy should be started whenever a mobile hyperechoic tumor originating from a calcified site, especially in the left-side of the heart is detected. The indications for emergency surgery are also a matter of controversy, when a tumor exhibits rapid growth despite appropriate medical therapy, complete surgical resection should be considered to prevent strokes or sudden death in patients with end-stage renal failure.

Chapter 48

ENDOVASCULAR TREATMENT OF
ACUTE ISCHEMIC STROKE

*T. Jonszta, M. Kuliha, M. Roubec, R. Herzig, D. Šaňák,
V. Procházka and D. Školoudík*

INTRODUCTION

Stroke is one of the most frequent causes of mortality, morbidity and disability of population in developed countries. [1, 2] Ischemic stroke (IS) represents 80 - 85% of all strokes in Europe and Northern America. The most often cause of IS is an acute occlusion of cerebral arteries, which can be demonstrated in more than 70% of patients in the first three to six hours after onset of symptoms. [3] Mortality of IS patients during the first month ranges between 10% and 17% and even up to 75% in patients with malignant infarction. [4] Finally, only about 30% of IS patients are independent after three months. [2] These facts support the importance of IS.

Table 1. Thrombectomy devices for acute stroke in use [14].

Device Class	Company Name	FDA Indication	In Clinical Use?
<i>Aspiration/Suction</i>			
Amplatz Thrombectomy	Ev3 Medical	Mechanical dissolution of thrombus within dialysis fistulae	No longer marketed
AngioJet	Possis	Breaking apart or removing of thrombus in peripheral veins or arterio-venous access conduits	Yes
NeuroJet	Possis	N/A	No longer marketed
Oasis Thrombectomy	Boston Scientific	Removing thrombus from hemodialysis access grafts	No longer marketed
Penumbra	Penumbra, Inc	Revascularization of patients with acute ischemic stroke	Yes
Vasco +35	Balt Extrusion	N/A	Not in U.S.
<i>Clot Retriever</i>			
Attractor-18	Boston Scientific	N/A	No longer marketed
Catch	Balt Extrusion	N/A	Not in U.S.

Table 1. (Continued)

Device Class	Company Name	FDA Indication	In Clinical Use?
In-Time	Boston Scientific	Retrieval of intravascular foreign objects in peripheral vascular, neurovasculature and cardiovascular	No longer marketed
MERCI	Concentric Medical	Restore blood flow in the neurovasculature	Yes
Phenox	Phenox GmbH	N/A	Not in U.S.
TriSpan	Boston Scientific	N/A	No longer marketed
<i>Ultrasonography</i>			
EKOS	EKOS Corporation	Infusion of fluids into peripheral vasculature	Yes
OmniWave	OmniSonics	Removal of thrombus and infusion of fluids into peripheral vasculature	No longer marketed
<i>Snare</i>			
Alligator	Chestnut Medici Technologies, Inc.	Peripheral and neurovasculature foreign body removal	Yes
Amplatz Gooseneck	Ev3 Medical	Retrieval and manipulation of atraumatic foreign bodls in coronary and peripheral cardiovascular system and the extra-cranial neurovascular anatomy	Yes
EnSnare Device	Merit Medici Systems, Inc.	Retrieval and manipulation of foreign objects in the cardiovascular system or hollow viscous	Yes
Device Class	Company Name	FDA Indication	In Clinical Use?
Neuronet	Boston Scientific	N/A	No longer marketed

EPAR - Endovascular Photoacoustic Recanalization, FDA—Food and Drug Administration, NA—not applicable, U.S.—United States

The location of cerebral artery occlusion and time to recanalization are known independent prognostic factors of IS. Early recanalization within six hours after onset of symptoms is associated with a significantly higher chance of independency after 90 days with a significant reduction of mortality [5].

In the last decade, the number of methods used for acceleration of artery recanalization strongly increased. In addition to pharmacological methods, especially intravenous (IVT) and intra-arterial thrombolysis (IAT) [6-8], mechanical (neuro-interventional) methods (i.e., Merci Retrieval System®, Penumbra System®, Solitaire® stent, Trevo Pro®, Catch device®, Phenox Clot Retriever®, BONNET Intracranial Flow Restoration Device®, pRESET Thrombectomy Retriever®, direct stent placement, EkoSonic™ Endovascular System, In-Time™ Retrieval Device, Amplatz Goose-Neck MicroSnare®, Attractor-18™, Neuronet™ Guidant device, LaTIS laser device®, Possis Angiojet system®) were tested and introduced into clinical practice similarly as in the treatment of heart ischemic syndromes—Table 1 [9-14].

Data from the meta-analysis of 53 clinical trials (including 2,066 patients) suggests that early recanalization is present only in 24.1% patients without specific treatment (spontaneous recanalization), 46.2% patients treated with IVT, 63.2% patients treated with IAT, 67.5% of patients treated with combined IVT - IAT and in up to 83.6% patients treated with mechanical methods [5]. Endovascular therapy as a new early recanalization option for patients with acute IS is currently intensely investigated. Nevertheless, the use of these methods only in specialized centers represents the main limitation.

Several thrombectomy devices will be introduced with results of studies and a list of ongoing trials.

THROMBECTOMY DEVICES

Merci Retriever (Concentric Medical, Mountain View, CA, U.S.)

The Merci Retrieval System® is a minimally invasive catheter-based system designed to retrieve and remove clots in patients experiencing acute IS. It was one of the first thrombectomy systems used in acute stroke patients. The Merci Retrieval System® consists of three parts: Merci retriever, Merci microcatheter and Merci balloon guide catheter—Figure 1.

The Merci Retrievers® are constructed from nitinol (nickel titanium) memory-wire and are corkscrew-shaped. This design is considered to be best suited for blood clot removal from large vessels within the neurovasculature. The Merci Retriever® is delivered through the dedicated Merci® MC18L microcatheter to the lesion location in its linear formation. Once deployed, the retriever returns to its coiled shape to ensnare and retrieve the clot. The Merci Retrievers are compatible with the Merci® Balloon Guide Catheter. This catheter comes in two sizes—namely 8 and 9F. The catheter has compliant silicone balloon mounted at its end. The balloon soft and atraumatic design provides temporary flow arrest in thrombectomy procedures when inflated. This should help to prevent distal embolization. One lumen is used to inflate and deflate the balloon, while the second lumen allows continuous access to the neuro vasculature.

There are currently ten Merci Retrievers® available to match different vessel sizes. The newest generation of Retrievers®, the V Series, incorporates features of the two earlier generations to create a best-in-class thrombectomy device. The V Series is designed such that the proximal loops stretch to engage the clot, while the two distal loops remain intact to capture the clot.

Merci Retrievers® are also indicated for use in the retrieval of foreign bodies misplaced during interventional radiological procedures in the neuro, peripheral and coronary vasculature.

The Merci Retriever® was first cleared for human use in 2004, by the Food and Drug Administration (FDA). Since 2004, the Merci Retriever® has been used in more than 14,000 patients throughout the world including the United States, Europe, Australia, Singapore and Canada, and since May 2010, also in Japan.

Figure 1. Merci V Retriever® (Concentric Medical, Mountain View, CA, U.S.).

Published Studies

Successive generations of the MERCI device have been reported in three prospective, single-arm, nonrandomized, multicenter feasibility and safety studies. In the MERCI-I trial, 28 patients were treated with this technique with 64% successful recanalizations. In the following prospective, nonrandomized, multicenter MERCI II trial, the safety and efficacy of a novel embolectomy device (Merci Retriever) to open occluded intracranial large vessels within eight hours of the onset of stroke symptoms were tested. All patients were ineligible for intravenous recombinant tissue plasminogen activator (rt-PA). Recanalization was achieved in 46% of patients on intention to treat analysis. This rate was significantly higher than 18% in historical controls of ($P < 0.0001$). Clinically significant procedural complications occurred in 7.1% patients. Symptomatic intracranial hemorrhages (SICH) were observed in 7.8% patients. Good neurological outcomes (defined as a modified Rankin scale [mRS] 0-2) were observed in 46% patients versus 10% in historical controls (relative risk 4.4, $P < 0.0001$) and mortality was in 32% patients versus 54% in historical controls (relative risk 0.59, $P < 0.01$) [15].

The results were confirmed in the Multi MERCI international, multicenter, prospective, single-arm trial. One hundred and sixty-four patients with large vessel IS who had received IV rt-PA but did not recanalize or who were ineligible for IV rt-PA and were treated within eight hours of symptom onset were included in the study. Treatment with the Retriever alone resulted in successful recanalization in 57.3% treatable vessels and in 69.5% after adjunctive

therapy (IA rt-PA, mechanical). SICH occurred in 9.0%. Clinically significant procedural complications occurred in 5.5% patients [16]. There was no definite association between time to treatment or reperfusion and outcomes in the unadjusted analysis. After adjustment for age, baseline NIHSS, and glucose, there was a strong trend toward fewer independent outcomes with later reperfusion times [17].

Final recanalization status was the strongest predictor of clinical outcomes in patients undergoing thrombectomy in presented studies. The ability to remove the clot was negatively influenced by systolic blood pressure [18].

Post hoc analysis with patients in the MERCI (68 patients) and Multi MERCI (81 patients) trials, who would have been eligible for PROACT II, showed a trend toward better clinical outcomes compared to the PROACT II control arm. In both unadjusted and adjusted analyses, mortality rates did not significantly differ between embolectomy patients and PROACT II control patients [19]. No statistically significant differences were found between patients with occlusion of M2-segment of middle cerebral artery (MCA) and M1-segment of MCA for symptomatic hemorrhage, clinically significant procedural adverse events, favorable 90-day outcome, or 90-day mortality. In multivariate analysis, final revascularization was the strongest independent predictor of good outcome at 90 days [20].

Further analysis showed that mechanical thrombectomy of acute intracranial internal carotid artery (ICA) occlusion using the Merci Retriever device, alone or in combination with adjunctive endovascular therapy, has a high rate of successful vessel recanalization (39%). Subjects with successful ICA recanalization by this method have improved post-stroke clinical outcome and survival compared with subjects in whom the ICA is not successfully recanalized [21]. Patients with vertebrobasilar occlusion in the MERCI and Multi-MERCI trials achieved recanalization in 78% cases, mortality was 44% and good outcomes were seen in 41%. Outcomes in these patients compared favorably with natural history reports. Patients with recanalization tended to have better outcomes than those without [22].

Penumbra System® (Penumbra Inc., Alameda, CA, U.S.)

Penumbra Inc.'s IS device platform, the Penumbra System® (Figure 2), is designed to revascularize or open up a blood vessel that is blocked by a blood clot. The Penumbra System® is FDA cleared and CE-marked. The system is based on a continuous aspiration thrombectomy platform. It includes reperfusion microcatheter that is connected to an aspiration pump through aspiration tubing, generating a suction force of -700 mm Hg. A teardrop-shaped separator is advanced and retracted within the lumen of the reperfusion catheter to debulk the clot for ease of aspiration. As a nonpharmacologic tool, it has the potential of reopening a vessel without the use of adjunctive thrombolytics, thus offering dual options for recanalization via a single access platform. In addition, the system is designed to minimize the need to blindly penetrate into the occluded vascular segment because it operates from the proximal end of the clot. Due to the flexibility and variety of available sizes (0.26 – 0.54 inch) of the reperfusion microcatheters, even smaller distal branches such as M2 and A2 can be successfully accessed for recanalization.

Published Studies

The phase 1 trial showed a 100% revascularization rate to TIMI 2 or 3 in 20 patients (21 vessels). The pivotal phase 2 trial, completed in September 2007, showed a TIMI 2 or 3 recanalization rate of 81.6% with a low periprocedural serious adverse event score of 3.4% in 125 patients treated with this device; none were device-related. SICH occurred in 11.2% of the patients, and all-cause mortality was 32.8%. Good neurologic outcome as (defined as a > 4 points improvement on the NIHSS score at discharge) was observed in 57.8% of the patients, whereas good functional outcome as defined by a 90-day mRS score of zero to two was reported in 25% of patients. Patients who were successfully recanalized by the Penumbra System® had generally better outcomes than those who were not [23,24].

Figure 2. Penumbra System® (Penumbra Inc., Alameda, CA, U.S.).

First single-center experiences as well as preliminary data from the first post-market multicenter study seemed to confirm these findings. In a retrospective case review study performed in 139 patients treated by the Penumbra System® at seven centers in the United States and Europe, the device was found to successfully recanalize the target vessel in 84% of cases, with similar outcome and intracranial hemorrhage rates as those in the pivotal trial. In fact, 40% of the patients had achieved a mRS score of ≤ 2 at 90 days, which is a significantly higher rate than that reported earlier [25]. Thus, it appears that the favorable safety and effectiveness profile of the Penumbra System® observed in the pivotal trial can be extended to the real-world setting.

Solitaire™ Stent (Ev3, Irvine, CA, U.S.)

Solitaire™ AB (FR) Neurovascular Remodeling Device is the only fully deployable and completely retrievable self-expanding stent designed for bridging the neck of aneurysms. It can be fully retrieved, even when fully deployed, repositioned and redeployed again—Figures 3 a,b.

Solitaire™ AB (FR) stent is deployed through a standard 0.021" or 0.027" micro catheter on a 0.016" pushwire, which means that Solitaire™ AB (FR) delivers just like an intracranial coil. It allows multiple retrievals, even after full deployment for adjustment and superior placement. It can be introduced easily even into very tortuous vessels. Its open slit, closed-cell design gives Solitaire AB an optimal radial force with good kink resistance. It can be deployed by electrolytic detachment. It is available in two diameters of 4 or 6 mm and lengths 26, 31 and 41 mm.

As per the manufacturer's recommendation, this stent is designed for the treatment of intracranial neurovascular disease. At first, it was intended for wide neck aneurysm treatment

only. At present, it is also renowned for its excellent results in intracranial vessel recanalization in stroke patients.

Figure 3 a,b. Solitaire™ AB (FR) Neurovascular Remodeling Device (Ev3, Irvine, CA, U.S.).

The unique Solitaire™ stent design features allow dual functionality: firstly, it acts as a temporary intracranial bypass providing immediate flow restoration through the thrombus after the temporary stent deployment. Secondly, it acts as a clot retriever, trapping thrombus into its cells allowing the clot removal. It received CE Mark approval as a flow restoration device.

Procedure

All procedures are performed via a femoral artery approach under sedation or in general anesthesia in extremely agitated patients. For the anterior circulation, an 8 Fr or 9 Fr Merci balloon guiding catheter (Concentric Medical, Mountain View, CA, U.S.) is introduced through a femoral sheath into the appropriate carotid artery. For the posterior circulation, a 6 Fr Envoy guiding catheter (Cordis, Miami Lake, FL, USA) is placed into the dominant, or navigable, vertebral artery. A 0.021 inch internal diameter microcatheter Prowler Select Plus (Cordis) or Vasco 21 (Balt, Montmorency, France) is navigated distally to the point of

occlusion over a 0.014 inch steerable microwire. A microcatheter angiographic run is then carried out in order to confirm and define the vasculature distal to the thrombus.

The Solitaire™ AB (FR) is introduced through the 0,021" microcatheter, and the device is deployed across the occluding thrombus. The microcatheter is then partially withdrawn, so that the distal marker is positioned at the exact level of the proximal marker of the stent. After the Solitaire™ AB (FR) deployment, an angiographic control is performed in order to evaluate the correct placement and expansion of the stent and to find out if there already is flow restoration past the occlusion site. After the angiographic run, the Solitaire™ AB (FR) is maintained in place for a few (three to seven) minutes to allow device expansion. After this time, the stent is slightly resheathed and then both the deployed Solitaire™ AB and the delivery microcatheter are gently pulled back together and recovered through the guiding catheter. Immediately after the retrieval, it is necessary to aspirate the content of the guiding catheter in order to remove any clot debris eventually present in the lumen of the guiding catheter. In case of unsuccessful thrombus removal, another attempt is usually indicated. After thorough cleaning of the stent, it can be reintroduced into occlusion site. If necessary, up to five passes are performed using the device. The integrity of the stent must be consistently checked after every pass. In case of repeated unsuccessful thrombus retrieval, suboptimal angiographic result in atherosclerotic lesions or inability to recapture the stent, a bail-out option of repositioning the stent is available following with permanent deploying it by electrolytic detachment, similar to coil. However, its radial force is not very high, and very often different types of stents need to be used to finish the procedure.

Mechanical thrombectomy also has its specific potential drawbacks. It usually takes a longer time compared to direct stenting. There is also increased risk of intimal injury to the vessel wall while withdrawing an unfolded stent to perform thrombectomy. It luckily proved to be of little concern in the clinical setting. However, microscopic studies have proved some minor intimal injuries in animal studies. Vasospasms and subarachnoidal hemorrhage have been described in clinical studies after thrombectomy with the Solitaire device.

Published Studies

Current reports with Solitaire device come from different European centers since the device is not currently approved in the United States. Castano et al. [26] reported their experience in the treatment of 20 patients with acute IS and large vessel occlusion in the anterior circulation. Recanalization grade TICI 2b/3 was achieved in 90% of treated vessels, and no procedural complications were reported. SICH occurred in 10% of patients, and 45% of them achieved a mRS ≤ 2 at three months. The device used in this study was the Solitaire AB stent, initially designed as an aneurysm neck bridging stent. The device was deployed for one or two min before retrieving it to perform embolectomy. Recanalization required in average 1.4 passes. The successful off-label use of this stent prompted the creation of the Solitaire™ FR device with minimal modifications from the AB version and specifically designed for treatment of acute IS.

Machi et al. [27] achieved successful recanalization in 50 out of the 56 patients (89%) treated with the Solitaire™ FR device. Procedure-related complications occurred in 9% of patients, and 46% of them achieved a mRS ≤ 2 at discharge. The mean number of passes required per procedure was two (1–5 range). The device was positioned across the area of

occlusion for three to seven min and then gently recovered into the guide catheter. Vasospasm during retrieval of the fully deployed stent was a common phenomenon; two patients had asymptomatic subarachnoidal hemorrhage and one patient, SICH.

Similarly, Roth et al. [28] treated 22 patients with acute IS and achieved TICI flow 2a/b or 3 in 91% of patients. Two SICH occurred, and 50% of patients achieved a mRS ≤ 2 at 90 days. Vasospasm after thrombectomy was noticed in three patients, and no device-related complications were reported.

Seifert et al. [29] reported experience with a Solitaire™ device in conjunction with IVT or IAT in four patients, achieving TIMI grade 2 to 3 recanalization in all patients and clinical improvement (median mRS, one at 30 days) in 50%. There was one death, and the other patient was lost to follow-up.

Investigators of the REscue, COmbined, and Stand-alone Thrombectomy (RECOST) study achieved TICI 3 flow in 84% of patients with acute IS treated with the Solitaire™ FR/AB device. [30] The aim of this study was to evaluate and appraise the timing, safety and efficacy of an integrated stroke management protocol. At three months, 54% of patients achieved a mRS ≤ 2 and 2% had SICH. The device was deployed for two to seven min in the target occlusion before thrombectomy.

CASE REPORT 1

A 74-year-old male was admitted to the hospital (stroke center) with left-sided hemiparesis, left-side facial palsy, dysarthria, eye deviation and neglect syndrome (NIHSS 14 points). Computed tomography angiography (CTA) finding confirmed T-occlusion of the distal ICA, anterior cerebral artery (ACA) and middle cerebral artery (MCA) on the right side. Atrial fibrillation treated with Aspirin® 100 mg daily, arterial hypertension and hypercholesterolemia were in medical history. Patient was treated with IVT (90 mg of rt-PA) 140 minutes after stroke onset. Patient's clinical status did not improve during IVT; therefore, he was transferred to angiography for mechanical recanalization. Persistent T-occlusion of the ICA was detected (Figure 4a). Successful thrombectomy with Solitaire™ device was performed, and the vessels were recanalized completely five hours after onset of symptoms (Figures 4 b-d). At discharge, patient presented with residual mild left-sided hemiparesis (mRS 2); small ischemic area in the right basal ganglia was shown by computer tomography (CT).

Trevo Pro® (Concentric Medical, Mountain View, CA, U.S.)

The Trevo System® is a non-deployable, sized 4 x 20mm stent-like device currently used in Europe and Canada. Its body is very soft and allows easy navigation through tortuous vessels, and its distal closed-end is intended to prevent vessel perforation—Figures 5 a,b. The device can be used in vessels ranging from 1.5 to 3.5 mm in diameter. The orientation of the stent struts has the thinner portion of the struts facing the vessel lumen in order to optimize thrombus incorporation, opposite to the design of stents used to treat intracranial aneurysms or intracranial atherosclerosis.

Figures 4 a-d. Recanalization of middle cerebral artery using Solitaire™ stent: Distal occlusion of internal carotid artery (4a). Solitaire stent deployed in the middle cerebral artery - flow restoration also called temporary bypass (4b). Middle cerebral artery recanalization after successful thrombectomy (4c). Solitaire stent immediately after extraction with thrombi in stent struts (4d).

The Trevo System® is being introduced into the occluded vessel via a 0.021” inner diameter large microcatheter. The deployment and clot extraction should be performed in a similar manner to that of Solitaire™ stent. The system is currently under investigation in pivotal study named Trevo 2 Clinical Trial. [31]

Mendonça et al. published results of a prospective study with 13 acute stroke patients (eight patients with MCA and five patients with ICA occlusion) treated by Trevo system®. Revascularization was achieved in 77% patients without periprocedural complications. Four patients (30%) died during the 90-day follow-up period and four patients (30%) achieved functional independence [32].

Figure 5 a,b. Trevo Pro® (Concentric Medical, Mountain View, CA, U.S.).

2.5 Catch Device® (Balt Extrusion, Montmorency, France)

The Catch Device® owes its design to Leo stent and is made of Nitinol. In fact, it looks like tiny wire basket intended for thrombus retrieval—Figure 6. Its external diameter is 4 millimeters, and the device is intended for use in vessels of diameter up to 5 millimeters. This device must be introduced exclusively by microcatheter Vasco+21, which has internal diameter of 0.0236". The microcatheter must be positioned at least 2 cm downstream behind the thrombus. Then the basket is opened, and the whole system can be withdrawn through 6F guiding catheter. However, the Catch basket cannot be resheathed into the Vasco microcatheter. Mourand et al. published results of retrospective study with 40 consecutive acute IS patients. Recanalization (TIMI grade 2 – 3) was achieved in 65% cases. SICH occurred in 18% cases. Periprocedural complications occurred in 15% patients without clinical consequences: four clot fragmentations and two vasospasms. Good functional outcome (mRS ≤ 2) after 90 days was achieved in 39% patients. Good functional outcome at 90 days was more frequent (56.5 vs. 7.7%), and mortality rate was lower (30.0 vs. 61.5%) in patients with successful recanalization in comparison with patients with unsuccessful recanalization [33].

Figure 6. Catch device® (Balt Extrusion, Montmorency, France).

Phenox Clot Retriever® (Phenox GmbH, Bochum, Germany)

This Germany-based company offers a whole range of unique-design mechanical thrombectomy systems.

Phenox clot retriever - pCR® is a device with a brush-like structure—Figure 7. The fibre structure made from nylon (polyamide) filaments increases in diameter from proximal to distal end. The fibres have also X-ray markers at the both distal and proximal ends. The fibre work, which has large surface area for efficient thrombus removal, is connected to a three-meter-long guiding wire, which is introduced into the body through a micro-catheter. This system is 22 millimetres long and is available in three different diameters intended to treat vessels ranging in diameter from 1 to above 3 millimeters. The pCR is introduced through microcatheter. Upon deployment behind the occluding thrombus, the filaments unfold, and the thrombus is captured in the fibre network. The system is then gradually withdrawn into the guiding catheter under constant aspiration and removed.

Figure 7. Phenox clot retriever - pCR® (Phenox GmbH, Bochum, Germany).

Figure 8. CRC phenox Clot Retriever CAGE® (Phenox GmbH, Bochum, Germany).

CRC phenox Clot Retriever CAGE®, like the pCR, is made from a fibre work of polyamide filaments. In contrast to the pCR, the CRC possesses an additional Nitinol (nickel, titanium) thread cage at the proximal end of its fibre brush—Figure 8. This nitinol cage gives a higher radial range, which is an advantage against older and/or firmer thrombi. This system is available in two different sizes intended to treat vessels with diameter ranging from 2 to above 3 millimetres. Otherwise, the design of the polyamide fibres, central wire, insertion wire and system markers is identical to the pCR system. The system insertion, deployment and final thrombus removal is also performed in the same way.

Both the pCR and the CRC systems are intended for single extraction only, which means that they must be exchanged for different devices in case of first attempt extraction failure.

Bonnet Intracranial Flow Restoration Device® (Phenox GmbH, Bochum, Germany)

The BONNET Intracranial Flow Restoration Device® consists of a self-expanding nitinol braiding with polyamide filaments passing through the interior—Figure 9. These enlarge the surface area and enable better fixation of the thrombus mass. The instrument is firmly connected with an insertion wire, and carries X-ray visible markers at its proximal and distal ends. The size of this device is 5 x 35 mm.

The BONNET® has high flexibility and is easy to advance through tortuous vessels. It is also a repeatedly re-usable device. The system is advanced through microcatheter and should

preferably be deployed distally of the thrombus. However, it can also be released after withdrawal of the micro-catheter partially or completely into the thrombus. The micro-catheter does not have to be completely removed. The flow restoration is achieved through simultaneous withdrawal of the BONNET® and the micro-catheter through the guiding catheter. The system can either be put distally of the thrombus or can be released into the thrombus. Re-use in the same patient is possible, for example in another vessel blockage.

Figure 9. BONNET Intracranial Flow Restoration Device® (Phenox GmbH, Bochum, Germany).

Figure 10. BONNET short Intracranial Flow Restoration Device® (Phenox GmbH, Bochum, Germany).

The BONNET short Intracranial Flow Restoration Device® is a new variant of the trusted BONNET®. In addition to its new size, the system displays a new shape and a higher level of relative radial force. The BONNET short® consists of a self-expanding nitinol braiding with polyamide filaments passing through the interior—Figure 10. The system is firmly connected with an insertion wire in an eccentric attachment and carries X-ray visible markers at its proximal and distal ends. It enables a fast and safe intracranial vessel flow restoration also in curved vessel areas. Re-use in the same patient is possible, for example in another vessel blockage. Its size is 5 x 23 mm, and it is suitable for vessels larger than 2 mm. The technique of its deployment and withdrawal is the same as in BONNET system®.

CASE REPORT 2

A 48-year-old male suffered from sudden left-sided hemiparesis, left facial nerve palsy and dysarthria (NIHSS 10 points). Findings on brain CT six hours after stroke onset were negative; CTA detected M1-MCA occlusion. CT perfusion did not detect any signs of definitive cerebral infarction. Digital subtractional angiography confirmed right MCA occlusion with collateral flow from the ACA territory (Figure 11a). Mechanical thrombectomy with BONNET device was performed 40 min after admission to hospital and immediate recanalization of MCA was achieved (Figure 11b). Patient's clinical status substantially improved immediately after the vessel reopening. Patient was without neurological deficit (mRS 0) at discharge.

Figures 11 Continued

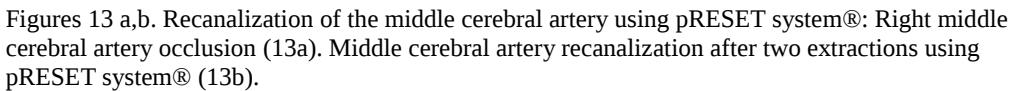

Figures 11 a,b. Recanalization of the middle cerebral artery using BONNET system®: Complete right middle cerebral artery occlusion with collateral flow from the anterior cerebral artery territory (11a). Successful middle cerebral artery recanalization using the BONNET system® (11b).

pRESET Thrombectomy Retriever® (Phenox GmbH, Bochum, Germany)

The pRESET Thrombectomy Retriever® is another brand new thrombectomy device. The laser-cut and self-expanding Nitinol-System allows effective removal of clot material from 2 to 4 mm vessel diameter. An optimized cell design and a helically shaped slit enable a constant cell size, even in smaller vessels. The closed “ring” design at the proximal end of the system ensures a stable opening, less tapering when withdrawn and radial force on a steady level—Figure 12. The pRESET features an excentric attachment to the insertion wire as well as X-ray visible markers at its proximal and distal ends. The System can be cleaned easily, and re-use in the same patient is possible. Its nominal size is 4 x 30 millimetres; it is delivered through 0.021” lumen microcatheter, and the technique of thrombus extraction is identical with previously described systems.

CASE REPORT 3

A 51-year-old male was admitted to the hospital with sudden left-sided hemiparesis and dysarthria (NIHSS 16 points). Chronic abuse of alcohol and nicotine were in patient history.

The recanalization rates clinical results of modern thrombectomy devices appear promising as the devices continue to evolve and become more operator-friendly. Baker et al. [34] screened citations for human studies of any design or case series or case reports of patients with an acute IS that evaluated a neurothrombectomy device and reported at least one clinical effectiveness outcome or harm. They identified 87 articles meeting eligibility criteria: 18 prospective single-group studies, seven noncomparative retrospective studies, and 62 case series or case reports. All prospective and retrospective studies provided data on successful recanalization. The recanalization rate widely varied (43 to 78% with the MERCI Retriever and 83 to 100% with the Penumbra System). SICH was evaluated in 16 studies and did not exceed 11%, and vessel perforation or dissection was between 0 and 7% and varied by device. Predictors of harm included older age, history of stroke, and higher baseline stroke severity scores, whereas successful recanalization was the sole predictor of good outcomes [34]. Unfortunately, the limitation of performed studies is missing evidence of a fragmentation, distal embolization, or relocation of the occlusive thrombus [35].

Three studies are underway in the United States and Europe to test retrievable stents in the treatment of acute IS. The Solitaire™ FR with the Intention for Thrombectomy (SWIFT) study is ongoing (recruitment completed) and will compare Solitaire FR with the Merci retriever in 200 patients. [36] The Trial and Cost Effectiveness Evaluation of IA Thrombectomy in acute IS (THRACE) study that will compare IVT with thrombectomy procedures using the Merci retriever, Penumbra system, Catch device (Balt Extrusion,

Montmorency, France), and the Solitaire™ FB stent in 480 patients. The Thrombectomy Revascularization of Large Vessel Occlusions (TREVO 2) study was recently started in the United States and will compare the Trevo system versus the Merci retriever in the treatment of acute IS. Approximately 178 patients will be enrolled in the study [37].

The aim of an ongoing IMS-III trial is to investigate whether a combination of IVT and IAT is superior to standard IVT (standard dose of 0.9 mg/kg rt-PA). If the thrombus is resolved, no additional intra-arterial therapy is administered. If the occlusion is still present, the additional intra-arterial treatment (max. 22 mg of rt-PA) will be administered. IAT might be combined with low-intensity ultrasound (US) via the EKOS® Micro-Infusion Catheter and thrombus-removal device as well. The clinical outcome is calculated by the mRS three months after the procedure. A total of 900 subjects will be enrolled in the study [38].

The ongoing Mechanical Retrieval and Recanalization of Stroke Clots Using Embolectomy (MR-RESCUE) trial aims to evaluate the efficacy of the standard IVT in case of proximal main branch occlusion in the anterior circulation compared to the efficacy of mechanical thrombectomy (with MERCI or Penumbra) within eight hours after stroke onset [39].

In the DWI/PWI and CT perfusion assessment in the triage of wake-up and late presenting strokes undergoing neurointervention (DAWN) trial, patients with large artery occlusion are selected according to the magnetic resonance imaging (MRI) or CT perfusion images more than eight hours after stroke onset. The treatment is initiated between eight and 24 hours [40].

Direct Stent Placement

Intracranial self-expanding microstents have been used successfully as temporary or permanent endovascular bypass in the invasive management of acute IS. It has been performed most commonly as a rescue procedure to displace thrombus or following early reocclusion after successful fibrinolysis. Angioplasty with stenting was originally described in acute stroke for underlying atherosclerotic stenosis after successful fibrinolysis.

With this technique, the stent deployed at the point of vessel occlusion expands, displacing circumferentially the thrombus and allows flow restoration. The re-establishment of flow through the occlusion site promotes immediate dissipation of prothrombotic factors. At the same time, the restored arterial flow allows thrombolytic medications to be in contact with thrombotic material trapped within the mesh of the stent and against the arterial wall.

Various stents have been used over time to bridge the occlusion site. The first report of coronary balloon-mounted stent placement into the basilar artery was published in 1999, by Phatouros et al. [41]. These procedures were associated with high periprocedural major complication rates (up to 50%). Gradually, self-expanding stents came into use. In the past, stenting was used after failure of different recanalization approaches, i.e., angioplasty, IAT and thrombectomy with a snare device.

Self-expandable stents were approved for vessel remodeling in the treatment of cerebral aneurysms and intracranial atherosclerotic disease. The Enterprise stent (Cordis Neurovascular, Miami Lakes, FL, U.S.), the Neuroform system (Stryker, Natick, MA, U.S.), and the Leo stent (Balt Extrusion, Montmorency, France) are devices introduced for stent-assisted coiling of wide-neck aneurysms. The latter stent is not marketed in the United States.

The Wingspan system (Stryker, Natick, MA, U.S.) was approved for treatment of intracranial atherosclerosis. Both the Neuroform and Wingspan stents have an open-cell design, whereas the Enterprise and Leo stents are closed-cell design—Figure 14. [42] The closed-cell design allows resheathing of the stent after partial deployment (70% for Enterprise and 90% for Leo).

These devices have been used off-label in the treatment of acute IS. The concept of flow restoration without clot removal has gained attention as other recanalization approaches that focus their strategy in thrombectomy have failed.

Published Studies

Fitzsimmons and Nelson reported one of the first cases of cerebral revascularization with deployment of a self-expansible stent. [43] A Neuroform stent was deployed in an occluded left MCA after the IA infusion of a glycoprotein (GP) IIb/IIIa inhibitor failed to recanalize the vessel. Multiple reports have followed, especially from the group lead by Levy et al. [44], who have pioneered the use of self-expansible stents in the treatment of acute IS. In 2007, they reported a 100% successful deployment of stents (16 Neuroform and three Wingspan stents) in the target occlusion, achieving a recanalization TIMI score 2 – 3 in 79% of lesions. Four (22%) patients had a mRS ≤ 3 at three months and two (11%) patients suffered SICH.

Most of the studies published to date have been retrospective single-center reports with sample sizes ranging between nine and 20 patients [45–49]. Although these cohorts are small, recanalization rates of 92 and 100% have been reported in cases where other thrombectomy devices have failed [46,47,49]. Another two small studies reported recanalization rates with cerebral angioplasty 60 to 90% and good outcomes (mRS 0 – 2 or NIHSS ≤ 4) between 36 and 74% [50,51]. Jovin reported successful recanalization in 23 out of the 25 patients, one SICH and one carotid dissection. [52]

The recently reported preliminary data of a prospective Stent-Assisted Recanalization in acute IS (SARIS) study of first 20 patients with acute IS showed the successful recanalization (TIMI grade 2/3) in 100% of cases with a 5% rate of SICH. [53] A six-month follow-up of the SARIS trial found mRS ≤ 2 in 55% of patients with a mortality rate of 35%. None of the patients had in-stent restenosis and all had TIMI-3 flow in angiographic follow-up [54].

There is growing experience with intracranial stenting in the acute IS setting, which has brought encouraging findings. Stenting is technically feasible, as reported up to 100% successful deployment rate of different studies. Acute in-stent thrombosis is rare, and different treatment strategies may be used to achieve stent recanalization: intra-arterial administration of GP IIb/IIIa inhibitors or stent resheathing. Enterprise stents appear to have better navigability than the Wingspan and Neuroform stents, especially in acute IS patients who generally have a tortuous anatomy with atherosclerotic changes. Self-expanding stents have enough radial force to recanalize occluded arteries. Angiographic outcomes have improved since the first series published by Levy et al. achieving TIMI 2/3 flow in more than 90% of lesions. Antiplatelet agents such as aspirin and clopidogrel or GP IIb/IIIa inhibitors should be administered prior to stent deployment to avoid acute in-stent thrombosis. However, this may lead to SICH if thrombolytic agents have been previously administered.

Figure 14. Enterprise stent (Cordis Neurovascular, Miami Lakes, FL, U.S.).

Intracranial stenting in acute IS patients certainly has many potential drawbacks. Permanent stent deployment in the setting of acute IS requires platelet inhibition to reduce the possibility of in-stent thrombosis. Intra-procedural administration of GP IIb/IIIa inhibitors or inhibitors of platelet function (Anopyrin®, Cardegic®) may increase the risk of hemorrhagic transformation. Furthermore, dual antiplatelet therapy is continued for at least the initial three months after the procedure. This is particularly worrisome in patients who already have been treated with IVT and/or IAT. Stent placement in acute IS is a permanent implant to resolve a temporary occlusion that may be caused by an embolus. Stent deployment may over time result in delayed in-stent stenosis. With expansion of the stent, the thrombus material may be pushed into perforating arteries. This phenomenon, described as “snow-plowing,” may explain strokes in perforator territories once the main artery has been recanalized and may pose another drawback of this technique.

CASE REPORT 4

A 61-year-old female suffered from sudden loss of consciousness, dysarthria and right-sided hemiparesis (NIHSS 15 points). Only hypercholesterolemia was in medical history. CTA revealed the occlusion of the left M1-MCA. Patient was treated with IVT (80 mg of rt-PA) 115 minutes after stroke onset without improvement of the clinical status. Persistent occlusion of the MCA was detected on angiography (Figure 15a). Left MCA was recanalized using cerebral percutaneous angioplasty with intracranial stent implantation three hours and 50 minutes after symptoms onset (Figure 15b). Follow-up brain CT detected infarction in the left basal ganglia. On discharge, patient presented with severe right-sided central hemiparesis and global aphasia (mRS 5).

Figures 15 a,b. Recanalization of the distal occlusion of the internal carotid artery and the middle cerebral artery using cerebral percutaneous angioplasty and stenting: Distal occlusion of the internal carotid artery demonstrated on angiography (15a). Recanalization of the internal carotid artery and the middle cerebral artery after direct intracranial stent deployment (15b).

CASE REPORT 5

A 77-year-old male suffered from vertigo and vomiting, gradual progression of dysarthria and left-sided hemiparesis. Arterial hypertension and diabetes mellitus were in medical history. Severe basilar stenosis was detected on CTA performed two hours and 50 minutes after stroke onset. Upon transfer to angiography, tachypnoe, worsening of consciousness and quadriparesis evolved. Patient was intubated and angiography detected left vertebral artery stenosis and basilar artery occlusion (Figure 16a). Attempt to recanalize the occlusion was

undertaken 3.5 hours after onset of symptoms. However, the procedure failed with contrast media paravasation at the site of vertebral intradural segment dissection caused by microwire (Figure 16b). Follow-up CT scan revealed ischemic changes in the pons and cerebellum and subarachnoid bleeding in posterior fossa. Patient was discharged in a poor clinical state (mRS 5).

Figures 16 a,b. Complications during recanalization of the basilar artery occlusion: Diffuse left vertebral artery atherosclerotic lesions with severe stenosis of V3-segment of left vertebral artery and artery occlusion distal to posterior inferior cerebellar artery origin (16a). Severe paravasation after iatrogenic vertebral dissection caused by microwire passage (16b).

Endovascular Sono-Lysis—EkoSonic™ Endovascular System (EKOS Corporation, Bothell, WA, U.S.)

Although the complex effect of ultrasound on the acceleration of thrombus lysis is not yet fully understood, it is assumed that the ultrasonic waves accelerate enzymatic fibrinolysis by primarily non-thermal mechanisms—increasing the transport of fibrinolytic agents into the thrombus by mechanical disruption of its structure [55], direct activation of fibrinolytic enzymes, either mechanical breaking of the complex molecules, in which fibrinolytic enzymes are inactivated by binding to their inhibitors, or irritation of the endothelium with increased production of fibrinolytic enzymes [56,57], transient peripheral (capillary) vasodilatation caused probably by increased production of nitrite oxide in the endothelium [58,59]. Radiation force and acoustic cavitation are the next possible and discussed mechanical effects of ultrasound [60].

There are two possibilities for sono-lysis application—transcranial approach through intact skull or intravascular approach.

The EkoSonic™ Endovascular System (EKOS Corporation, Bothell, WA, U.S.) is intended for targeted local drug delivery including rt-PA where non-cavitation, high-frequency, low-power microsonic energy allows better penetration and attachment of a thrombolytic agent into the thrombus, resulting in faster lysis and a vessel recanalization, as was proved by manufacturer in in vitro testing—Figure 17 a,b. The system consists of a single-use EKOS MicroLys US infusion catheter intended either for neurovascular interventions EkoSonicSV™ (3F/150 cm catheter inserted over a 0.014" wire) or for peripheral procedures EkoSonic™ (over a 0.035" wire). The outer diameter of the catheter is rather small and can be easily introduced through 6F guiding catheter, which is advantageous compared to some other devices. The catheters have a hollow end-hole infusion lumen incorporating cylindrical piezo transducer at its tip, which converts high-frequency energy into ultrasound waves. In EkoSonicSV™, the transducer power output is 0.45 W at a frequency of 1.4 – 1.9 MHz. The energy deployment causes non-cavitation fibrin strands thinning, loosens up the fibrin matrix and thus increases the availability of plasminogen activation receptor sites for plasminogen/plasmin binding. Bound plasminogen/plasmin is then protected from α_2 -antiplasmin inhibition. According to the manufacturer's data, thrombus exposed to ultrasonic pressure absorbed 48% more rt-PA in one hour than in conventional catheter local drug delivery. The clot lysis is four times faster than with the conventional catheter-directed thrombolysis alone in manufacturer in-vitro experiments. It has been suggested that EkoSonicSV™ dissolves a clot more homogeneously and completely with minimal residual thrombi and a low risk of distal embolism by dislocated clot fragments. There is a thermoreceptor placed at the catheter tip for continuous intraprocedural temperature monitoring. Increase in temperature may indicate vessel patency or local accumulation of energy in the clot and surrounding tissues by ultrasound waves. Since the output power and catheter temperature are continuously monitored, this therapy poses a low risk of the vessel wall and surrounding tissue damage and impairment. Due to these reasons, the vessel patency is reached faster with the smaller total doses of thrombolytic agents when compared to standard thrombolysis.

The other part of the system is the central unit, which generates the specific frequency energy and monitors the output power, along with the temperature of the catheter tip—Figure 17 a,b.

Figure 17 a,b. EkoSonic™ Endovascular System (EKOS Corporation, Bothell, WA, U.S.).

Published Studies

A phase I trial reported preliminary results of treatment using the EkoSonicSV™ system in 14 patients with 60% recanalization at 60 minutes, despite treatment of large clot burdens in some patients [61]. The device was tested again in the Interventional Management of Stroke (IMS) II with promising results [62]. Complete recanalization was achieved within 60 and 120 minutes in 12 (41%) and 20 (68.9%) patients, respectively. The authors compared their results with the findings from the IMS-1 clinical trial. They concluded that recanalization has been achieved in seven (30.4%) of the 23 control patients from the IMS-1 trial. Pooled analysis based on the results of these two studies showed complete recanalization

in 120 minutes in 68.9% of patients in the EkoSonic™ catheter sonography group compared with 53.3% of patients treated by standard microcatheter infusion technique. Due to these promising results, acute stroke in NINDS rt-PA-funded IMS III trial globally, which is currently enrolling at 60 stroke centers worldwide [38]. Furthermore, the SICH occurred in 8/81 (9.9%) subjects in the IMS-II, including 1/26 (3.8%) patients treated with IV rt-PA alone and one in a sonography microcatheter-treated subject without the use of sonography. No direct vessel perforation, primary subarachnoid hemorrhage, or intracranial dissection was documented in the treated subjects.

According to the authors' experiences, the EkoSonic™ catheter is easy to introduce despite the non-flexible sonography transducer located at its distal tip [63]. The authors did not encounter any detectable distal embolization potentially resulting from device manipulation. However, the risk of distal embolization was an issue in Janjua's study [64]. Although the distal emboli were observed in their study, this situation did not have any significant clinical consequences. On the other hand, distal embolisation was not detected in other studies [65,66]. The clot resolution time in patients presented by the authors (vessel patency in 35 minutes) was much quicker than in the IMS-2 study, where complete resolution of a clot was achieved after one hour in 41.1% of patients. One may speculate that such a promising result may be caused by the fresh (noncrossed-linked) nature of the clot.

CASE REPORT 6

Figures 18a-e. Continued on next page

Figures 18a-e. Continued on next page

Figures 18a-e. Recanalization of the basilar artery using intravascular sonolysis by EkoSonicTM Endovascular System. CT angiography detected severe proximal basilar artery stenosis in junction of vertebral arteries and occlusion of distal part of basilar artery; the tip of basilar artery and posterior cerebral arteries are perfused through the posterior communicating arteries collateral blood flow (18a). Angiographic finding of basilar artery occlusion via the left vertebral artery (18b). Cerebral percutaneous transluminal angioplasty with Wingspan stent 3,5 x 15 insertion to the proximal basilar artery stenosis and EkoSonicTM microcatheter sonolysis 35 minutes after rt-PA administration (18c). Follow-up CT angiography (maximum intensity projection—MIP) showed patent basilar artery with stent and normal filling of bilateral anterior inferior cerebellar artery, superior cerebellar artery and posterior cerebellar artery. Severe stenosis of the right vertebral artery is apparent (18d). CT scan at day two showed infarctions in the left pons and in the right posterior cerebral artery territory - calcarine artery feeding territory (18e).

A 60-year-old female was admitted to a local hospital with right humeral neck fracture. Four hours later, while being on a conservative therapy regime, she was suddenly unable to speak, and right-sided hemiplegia was diagnosed (NIHSS 19 points). Arterial hypertension, hypercholesterolemia, ischemic heart disease with coronary bypass and diabetes mellitus were in medical history. The immediate CT scan was negative for signs of ischemia and haemorrhage. CTA showed severe stenosis of both vertebral arteries at the junction level and basilar artery occlusion (Figure 18a). CT perfusion scans revealed prolonged time to peak value in the posterior fossa structures and occipital lobes of the brain. No substantial changes in blood volume and blood flow parameters were observed. The patient was transferred to angiography, which confirmed findings of basilar artery occlusion via the left vertebral artery. Intracranial stent Wingspan 3.5/20 mm (Boston Scientific, Fremont, CA, USA) was placed into the proximal basilar artery stenosis (Figure 18c). Thereafter, the EkoSonic™ catheter insonation was performed (Figure 18c) and completed successful basilar artery recanalization eight hours after stroke onset was achieved (Figure 18d). Follow-up CT revealed small brainstem infarction (Figure 18e). At discharge, residual dysarthria and right-sided central hemiparesis persisted (mRS 4).

Other Experimental Devices EPAR®—Endovascular Photoacoustic Recanalization (Endovasix Inc., Belmont, CA, U.S.)

EPAR® is a mechanical clot fragmentation device based on laser technology (endovascular photo-acoustic reanalization—EPAR®). This device consists of three French hydrophilically coated microcatheters with five windows at its tip, each of them with one optic fiber. The photonic energy, delivered at a rate of 1,000 optic pulses per second, is converted into acoustic energy at the fiberoptic tip of the catheter. This in turn creates micro-cavitation bubbles. The cavitation pockets undergo expansion and subsequent collapse and should create suction of the thrombus through the lateral windows into the catheter tip. Inside the tip, the clot is emulsified, and the tip contents are discharged as subcapillary-size particles (in vitro: 1 to 10 µm). This system is intended as fast clot emulsifier rather than laser-ablation device. The main objective is to provoke mechanical thrombolysis and reduce the amount of pharmacological thrombolytics needed.

Studies

Thirty-four patients (median NIHSS 19) were enrolled in the study published by Berlis et al. [67]. Ten patients had ICA occlusion, 12 patients MCA occlusion, 11 patients vertebrobasilar occlusion, and one patient posterior cerebral artery occlusion. The overall recanalization rate was 41.1%. Complete EPAR® treatment was possible in 18 patients (median NIHSS 18), with vessel recanalization achieved in 11 patients (61.1%) after EPAR. The average time of procedure was 9.65 minutes. Incomplete EPAR® treatment (16/34, median NIHSS 19) was defined as intention to treat with EPAR® and that the EPAR® microcatheter entered the patient. Additional treatment with IA application of rt-PA was used in 13 patients. An adverse event associated with the use of the device occurred in one patient. SICH occurred in two patients (5.9%). The mortality rate was 38.2%. Unfortunately, this device is not marketed any longer.

Revive™ SE Blood Clot Retrieval® (Codman and Shurtleff, Inc., Johnson and Johnson Company, Raynham, MA, U.S.)

Revive™ SE® is intended as a blood clot retrieval and removal device. Its self-expanding nitinol basket should act as a temporary bypass across the occlusion and subsequently can be used for thrombus removal. It is introduced via a microcatheter directly into or beyond the lesion and can be redeployed several times. It is designed as a closed distal end basket that should engage the clot effectively and prevent it from distal embolisation.

The company received CE Mark approval for the Revive™ SE® in February 2011. The device is not approved for distribution in the United States.

Pilot results of ten patients with acute large vessel occlusions treated with the Revive device was published by Rohde et al. Vessel recanalization (TICI 2b or 3) was successful in all patients without device-related complications. After one month, six patients had a clinical improvement of >8 points or an NIHSS 0 – 1; three patients died. SICH occurred in two patients. [68]

This device is going to be investigated in a single-arm German study named RIVER I (Reperfuse Ischemic Vessels with Endovascular Recanalization). The patients will be screened before the procedure with MRI imaging.

Penumbra Separator™ 3d® (Penumbra, Alameda, CA, U.S.)

Penumbra Separator™ 3D® is a brand new product that was introduced in January 2012, dedicated for thrombus retrieval in acute stroke patients. Its design resembles complex 3D “basket.” Its inner struts and complex design is aimed at firm thrombus engagement and reliable retraction. Like other stentriever, it is deployed into the occluded vessel segment with micocatheter, and retrieval is bolstered by active aspiration via guiding catheter.

At ABC-WIN Seminar, Prof. M. Knauth presented the European evaluation data on Separator 3D [69]. The first preliminary data from six European centers with this new device showed an approximately 90% successful recanalizations and good deliverability even in tortuous vessels.

Mindframe Capture LP® (Mindframe Inc., Irvine, CA, U.S.)

MindFrame capture LP® is another stent-like device aimed at temporary by-pass reopening of the occluded vessels and effective thrombectomy—Figure 19.

Its advantage is compatibility with 10/14 microcatheters with inner diameter from 0.0165 inch. It received an CE mark in August 2011, and first results in treating stroke patients were presented by Tommy Andersson, MD, PhD, Department of Neuroradiology, Karolinska University Hospital, Stockholm, who stated that this devices allowed good ability to access thrombus through tortuous blood vessel anatomies and showed fair recanalizations rate (personal communications).

Acandis APERIO® System (Acandis GmbH and Co. KG, Pforzheim, Germany)

Acandis APERIO® System is a self-expanding stent-like clot retrieval system that can be deployed through 0.027" inner lumen microcatheter and bolsters superb trackability and good thrombus removal rate of about 80%—Figure 20. No published data are available so far.

Possis Angiojet System® (Possis Medical, Minneapolis, MN, U.S.)

This is a five-Frech system based on rheolytic thrombectomy effect, caused by fast high-pressure saline jets that creates distal Venturi suction and leads to clot fragmentation and aspiration. First case reports of ICA recanalization procedures with this device were published [70].

Figure 19. Mindframe capture LP®.

Figure 20. Acandis APERIO System®.

Latis Laser Device® (Spectanetics, Colorado Springs, CO, U.S.)

This is also a microcatheter with laser at its tip. Contrast media injection was used for energy transfer from the catheter into the thrombus. The safety and feasibility study was

stopped after enrollment of only 12 patients, since there were difficulties in deployment of the catheter to the level of occlusion. This device is not marketed any longer.

Amplatz Goose-Neck Microsnare® (Ev3 Medical, Plymouth, MN, U.S.)

The system consists of microcatheter, snare and rotator. The microsnare is constructed of a nitinol cable and gold plated tungsten loop. This nitinol snare was used for clot retrieval in cases of solid thrombus with firm consistency. In cases of soft thrombus, multiple passes of the snare through the thrombus were used to disrupt its structure.

Attractor-18™ (Boston Scientific/Target Therapeutics, Fremont, CA, U.S.)

Another so called “goose-neck” snare, primarily developed to retrieve dislodged coils during cerebral aneurysm coiling procedure. Both these devices were not originally intended for thrombectomy in IS patients.

Neuronet™ Guidant Device® (Guidant Corp, Temecula, CA, U.S.)

Neuronet is a self-expanding basket introduced distally to a clot by a microcatheter. After it unfolds, it is retracted back into the thrombus and should pull the thrombus into the micro catheter.

In-Time™ Retrieval Device® (Boston Scientific, Boston, MA, U.S.)

The principle of clot removal is the same as in the Neuronet Guidant device.

Interventional Procedure Technique

In the authors' department, most of the procedures are performed under conscious sedation or under general anesthesia. Common femoral artery is the most common access site. In a few patients, in whom iliac arteries were occluded, the recanalization procedure was performed via brachial access. Mostly 6F or 8F sheath and 4F diagnostic catheters introduced over hydrophilic wires are used. As the first step, brain supplying vessels angiography is performed to evaluate the site of occlusion and extent of collateral supply. When endovascular recanalization is indicated, the 6F or 8F guiding catheter is inserted into the ICA or the vertebral artery. Subsequently, microcatheter supported by microwire sized 0,010” to 0,018” is inserted into the occlusion site. The authors try to navigate the microcatheter past the occlusion site to verify the lengths of the occlusion and to check if distal embolization is present. It is an absolutely duty to perform control microcatheter angiography after passing the occlusion to confirm the intraluminal position of the catheter and to exclude any vessel dissection or perforation. Having done this, the decision as to which of the recanalization

methods will be engaged for this particular case is made. This requires exchange of the catheter for the particular dedicated device. The interventionalist has to have more endovascular devices in store, since every patient is unique and the recanalization must be well tailored for the particular situation. Usually, 50 I.U. per kilogram (max. 3000 I.U.) of Heparin® are administered at the beginning of the procedure to prevent clot formation on introduced equipment. Furthermore, heparinized saline is used to continually flush all coaxial systems. Although some authors discourage the use of Heparin®, the authors have not encountered any substantial bleeding into the ischemic brain tissue over the past six years.

To conclude, the way of microcatheter introduction into intracranial vessels is standardized at the authors' institution and does not differ much between various intracranial endovascular procedures performed with different devices.

After successful artery reopening, any possible residual restenosis (or residual stenosis) at the original occlusion site should be precisely evaluated and treated if needed. The other very important issue is to evaluate distal arteries patency. Any distal embolization or residual occlusion has to be excluded. If eligible, patients with reocclusion are treated with IA rt-PA administration. Last, but not least, the proximal parts of the brain supplying vessels should be evaluated and treated if needed.

CONCLUSION

Early recanalization is associated with a significantly higher chance of independency after 90 days, with a significant reduction of mortality. In addition to pharmacological methods (IVT and IAT), mechanical neuro-interventional methods are intensively tested and introduced into clinical practice. Results of first studies showed safety and efficacy of various devices with increasing recanalization rate and relative low number of peri-procedural complications and SICH. However, clinical benefit for acute stroke patients has to be confirmed in prospective studies.

Chapter 49

METABOLIC SYNDROME, SUBCLINICAL CAROTID ATHEROSCLEROSIS AND RISK OF STROKE: HOW STRONG IS THE LINK?

David Della-Morte^{1,2} and Tatjana Rundek^{1,*}

IRCCS San Raffaele, Rome, Italy

ABSTRACT

The metabolic syndrome (MetS) is a distinctive phenotype with clustering of risk factors associated with an increased risk of vascular disease. MetS is reaching epidemic proportions worldwide. MetS and its components (hypertension, insulin resistance, dyslipidemia, and obesity) are established risk factors for stroke. Surrogate markers of subclinical carotid atherosclerosis such as carotid intima-media thickness (cIMT), carotid plaque (CP) presence and morphology, and carotid artery stiffness (STIFF) also have been linked to an increased risk of stroke. As multiple risk factors increase risk of vascular disease more than the sum of accompanying single risk factors, MetS has significant effects on development of atherosclerosis. Proinflammatory state and oxidative stress induced by MetS play a pivotal role in the carotid artery wall damage. MetS is an independent determinant of cIMT in both sexes, and predicts cIMT progression in large cohorts comprised of different race-ethnicities. Moreover, MetS has been demonstrated to significantly increase STIFF and to be a significant predictor of CP in multi-ethnic populations. Controversially, presence of MetS was not associated with cIMT and CP independent of other cardiovascular risk factors in individuals with optimal, normal, or high-normal blood pressure. Recently, a major issue has been whether MetS is a valid indicator of vascular risk, although from a clinical perspective, it serves a useful purpose to focus on individuals at high risk for developing vascular disease and type 2 diabetes. The development of non-invasive ultrasound methods capable of quantitatively evaluating atherosclerosis has provided an opportunity to

understand the early determinants of atherosclerosis and has improved our ability to detect individuals at high risk for stroke including individuals with MetS. Therefore, exploring and understanding the link between MetS and subclinical atherosclerosis could help further risk-stratify individuals with MetS, design new strategies to prevent stroke, and to determine the predominant components of MetS associated with carotid atherosclerosis in order to develop new and effective antiatherosclerotic therapies.

1. WHAT IS METABOLIC SYNDROME?

Metabolic syndrome (MetS) is a complex disorder considered a worldwide epidemic. [1] MetS is defined by a cluster of interconnected factors that increase the risk of atherosclerosis, cardiovascular diseases (CVD), stroke, and diabetes mellitus type 2 (DMT2). Its components are dyslipidemia (elevated triglycerides and apolipoprotein B (apoB)-containing lipoproteins, and low high-density lipoproteins (HDL)), elevation of arterial blood pressure (BP) and impaired glucose homeostasis, with abdominal obesity and/or insulin resistance (IR). [2]

More recently, other factors such as proinflammatory state, oxidative stress, and non-alcoholic fatty liver disease have been suggested to play an important role in MetS, making its definition even more complex. [2] Therefore, besides its clinical implications, there is still no a full consensus on pathogenic mechanism or defined diagnostic criteria for MetS. The scientific community still is debating whether MetS represents a specific syndrome or just a surrogate of combined risk factors that increase the risk for stroke, CVD and DMT2.

Since the first definition of Syndrome X given by Reaven that hypothesized a central role of vascular risk factors in the development of CVD and DMT2, [3] many international organizations and expert groups, such as the World Health Organization (WHO), the European Group for the study of Insulin Resistance (EGIR), the National Cholesterol Education Program Adult Treatment Panel III (NCEP:ATPIII), the American Association of Clinical Endocrinology (AACE), the International Diabetes Federation (IDF), and the American Heart Association/National Heart, Lung, and Blood Institute (AHA/NHLBI), have attempted to incorporate the different parameters to define MetS (definitions from these organizations have been well reported on [2]).

Briefly, in 1998 the WHO proposed that MetS may be defined by the presence of insulin resistance (IR) or DMT2, as essential components of the syndrome, along with at least two of the following parameters: raised BP, hypertriglyceridemia and/or low HDL-cholesterol, obesity (as measured by waist/hip ratio (WHR) or body mass index (BMI)), and microalbuminuria. [4] Subsequently, the EGIR excluded microalbuminuria from the syndrome while included hyperinsulinemia, and waist circumference (WC) as the main indicator to assess obesity. [5] In 2001, the NCEP:ATPIII published new criteria that included WC, blood lipids, BP, and fasting blood glucose (FBG).[6]

The IDF along with AHA/NHLBI particular emphasized abdominal obesity as a prerequisite of the diagnosis of MetS [7,8] with the goal to better predict risk for stroke, CVD, and DMT2. However, abdominal obesity was defined differently: the IDF recommended that the threshold for WC in Europeans should be 94 cm for men and 80 cm for women, while the AHA/NHLBI recommended cut-off points of 102 and 88 cm, respectively.

Currently, the two most used definitions for MetS are those of the NCEP:ATPIII and IDF specifically focused on WC as a surrogate measure of central obesity. However, a major

problem with these definitions has been their applicability to different ethnic populations, especially when trying to define obesity cut-off values. For example the risk of DMT2 is different across the Western and Eastern populations. To overcome these difficulties the Joint Interim Statement [9] suggested that there should not be an obligatory component, but that waist measurement would continue to be a useful preliminary screening tool. Three abnormal findings out of the proposed 5 would qualify a person for the MetS.

Based on these findings and considering the high incidence of stroke, CVD and DMT2, more practical and useful definitions for MetS should be proposed. The updated clinical guidelines for cholesterol testing and management (ATPIV) from the Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults are under development and due for publication in 2012. http://www.nhlbi.nih.gov/guidelines/cvd_adult/background.htm

2. METABOLIC SYNDROME AND RISK OF STROKE AND DIABETES

Metabolic Syndrome and Risk of Stroke

CVD is an important outcome in subjects with MetS. In fact, all the components of the various MetS definitions are involved in conferring risk of stroke and CVD. As expected, IR is more related to the risk of developing DMT2. In our study from a population-based multi-ethnic cohort of Northern Manhattan (the Northern Manhattan Study-NOMAS) in 1,509 individuals free of stroke, myocardial infarction (MI), and diabetes, IR, estimated by homeostasis model assessment (HOMA), was associated with a 2.8-fold increased risk of first ischemic stroke. [10] Using the same study population we have also showed the association between FBG and risk of stroke [11] and demonstrated that FBG was an independent predictor of vascular outcomes among individuals without diabetes. [12] Dyslipidemia and hypertension have been more associated with risk of stroke. [13,14] WC has been demonstrated to be associated with both stroke and DMT2. [15]

Several epidemiological studies have confirmed the increased risk of stroke in individuals with MetS, regardless of the diagnostic criteria used. The adjusted risk ratios for incident ischemic stroke associated with MetS range between 2.1 and 2.5 in prospective studies, and a hazard ratio as high as 5.2 has been reported. [16-18] Koren-Moraq et al. [16] using a cohort of 14,284 patients, demonstrated that patients with MetS without diabetes exhibited a 1.49-fold increased risk of ischemic stroke or transient ischemic attack (TIA), whereas those with frank diabetes had a 2.29-fold increased risk. The relative odds for ischemic stroke or TIA, associated with presence of MetS, were 1.39 in men and 2.10 in women. In the prospective Framingham cohort, both diabetes and the MetS were powerful risk factors, with a 10-year risk of ischemic stroke associated with diabetes of 14% in men and of 10% in women compared with 8% and 6% in nondiabetic men and women, respectively, with the MetS alone. [17] In a study where MetS was defined by the ATPIII criteria in 1,131 subjects with no history of CVD and diabetes, those with MetS had a 2.05-fold risk for all stroke and 2.41-fold risk for ischemic stroke, after adjusting for socioeconomic status, smoking, alcohol, and family history of coronary heart disease (CHD). The risk ratios among patients with MetS as defined by the WHO criteria were 2.08 and 2.47. [18] Although the data are similar across

studies, some still argue that the results from studies using different MetS definitions are not exactly comparable.

In NOMAS we found a significant association between the MetS and ischemic stroke risk, independent of other confounding factors including age, education, physical activity, alcohol use, and current smoking. [19] The prevalence of MetS in NOMAS was 49%, and differed by sex (39% in men, 55% in women, $p < 0.0001$) as well as race-ethnicity (56% in Hispanics, 41% in blacks, and 39% in whites, $p < 0.0001$). Interesting, the effect of the MetS on stroke risk was greater among women (HR=2.0; 95% CI, 1.3 to 3.1) than men (HR=1.1; 95% CI, 0.6 to 1.9) and among Hispanics (HR=2.0; 95% CI, 1.2 to 3.4) compared to blacks and whites. The etiologic fraction analysis estimated that elimination of MetS would result in a 19% reduction in overall stroke, a 30% reduction of stroke in women and a 35% reduction of stroke among Hispanics. Subsequently, using the same study population we confirmed that MetS was independently associated with all cardiovascular events, especially in subjects with both MetS and endothelial dysfunction.

Overall, these data strongly suggest that the risk of any incident stroke is increased in people with MetS and without history CVD and diabetes. [18]

However, fewer studies reported on the comparisons between MetS, its components, and various risk prediction scores on the risk of stroke and CVD. [20,21] In the Atherosclerosis Risk in Communities (ARIC) study, men and women with MetS were approximately 1.5 and 2 times more likely to develop ischemic stroke than control subjects after adjustment for age, smoking, LDL cholesterol, and race-ethnicity. However, comparison of receiver operating characteristic curves indicated that MetS did not considerably improve vascular risk prediction beyond the level achieved by the Framingham Risk Score (FRS). [21]

The reasons for discrepancy in these results are not quite clear but most likely they may have been due to the different cohorts studied, differences in the study designs (prospective vs. case control), as well as different MetS criteria used. To further explore these controversies, a meta-analysis was conducted on 21 prospective studies and showed that MetS was associated with the increased mortality from all CVD causes as well as with an increased incident CVD (RR 1.53; 95% CI, 1.26-1.87), CHD (RR 1.52; 95% CI, 1.37-1.69) and stroke (RR 1.76; 95% CI, 1.37-2.25). [22] The relative risk of CVD associated with the MetS was higher in women compared with men.

Putting together these findings, it is evident that patients with MetS have a greater risk of incident of stroke and other vascular diseases. Therefore we agree and support the proposed statement that *“a major breakthrough related to the concept of the MetS is the recognition of the high cardiovascular risk in subjects with a cluster of mild abnormalities or with a cluster of abnormalities that are not regarded as driving forces in CVD”*. [23]

Metabolic Syndrome and Risk of Diabetes

Patients with diabetes are at significant risk for CVD and vascular death. Approximately 65% of deaths in patients with diabetes are attributable to heart attack or stroke. [24] It is now well documented that MetS not only increases the risk for DMT2, but is also highly predictive of new onset DMT2. [25] Since impaired FBG and impaired glucose tolerance are components of the ATPIII and the WHO definitions of MetS respectively, this finding is not surprising. However some controversy still exist. A study conducted in 1,448 nondiabetic

individuals, demonstrated that the three components of the MetS were significant associated with risk of DMT2. These were insulinemia, the body size and lipids, whereas the BP was not associated with risk of DMT2. [26]

MetS criteria modify the ability of MetS in predicting DMT2. In 1,734 participants from the San Antonio Heart Study, [27] MetS predicted DMT2 independently of other factors. The ATPIII definition of MetS may perform better than the modified WHO definition. In a meta-analysis [28] the random-effects summary were 5.17 for the WHO definition (10 cohorts); 4.45 for the EGIR definition (4 cohorts); 3.53 for the ATPIII definition (13 cohorts); 5.12 for the AHA/NHLBI definition (5 cohorts); and 4.42 for the IDF definition (9 cohorts). These data suggest that a greater number of abnormal MetS components was strongly related to incident diabetes.

The major limitations to the results of these studies are the lack of accounting for other important factors that may be implicated in developing of diabetes. In particular, proinflammatory state and oxidative stress have been demonstrated to play a pivotal role in DMT2. [29,30] It is probable that along with the components of MetS described below, other mechanistic pathways may account for the residual CVD risk in MetS.

3. METABOLIC SYNDROME AND RACE-ETHNICITY

The prevalence of the MetS varies among ethnic groups. [31-33] According to the Third National Health and Nutrition Examination Survey, adult prevalence of the MetS was 32% in Hispanic-Americans, 22% in African-Americans and 24% in Caucasian-Americans. [32] Similarly, a prevalence of 24% among white subjects was reported in the Framingham Offspring Study, and a prevalence of 31% was reported among Mexican-American subjects in the San Antonio Heart Study. [33] Similar percentages have been reported also in other populations. [34,35]

Based on these findings it seems that blacks have a lower prevalence of MetS compared with other race-ethnicity. This is surprising since each of the MetS components is more frequent in African-Americans than in Caucasians. Several have been the proposed explanation for this paradox. It may be partly ascribed to the differences in IR and serum triglycerides in blacks when compared with other race-ethnicities. [36] In contrast, Hispanics have a high prevalence of the MetS compared to white and blacks. [37] One reason proposed is the high rates of IR, DMT2, and the prevalence of abdominal obesity and high triglycerides among Hispanics. [37]

Similar difficulties in using the MetS criteria were present also in analyses of Eastern populations. For instance, Asians tend to develop DMT2 while still maintaining “normal” WC values. [38] Therefore, applying the ATPIII guidelines to Asians was criticized for inaccurate estimation the prevalence of MetS.

However, the real reasons for the racial/ethnic differences in MetS prevalence still remain unknown. It is possible that the current definitions, criteria, and cut-off points underestimate the burden of components of MetS in different race-ethnicities. Therefore, it is important to reconsider the current classification of MetS by the NCEP, WHO, and IDF based on the characteristic of the studied populations. [39] In addition, besides variations in environmental factors, a different genetic susceptibility could explain these observed differences.

In a cohort consisted of 803 subjects from 89 Caribbean-Hispanic families enrolled in the Family Study of Carotid Atherosclerosis from NOMAS, we found a significant heritability for MetS and each of its components. [40] After adjusting for age and sex, the MetS had a heritability of 24% ($p=0.009$). When the components were treated as continuous traits, the estimates of heritability varied from 16% for systolic BP to 60% for HDL-cholesterol after adjusting for age, sex and appropriate medications. When the MetS components were analyzed as discrete traits according to ATPIII, the estimates of age and sex-adjusted heritability varied from 27% for large WC to 51% for low HDL-cholesterol levels. Other studies reported similar heritability estimates. [41,42] This evidence confirm that genetic factors contribute to the familial aggregation of the MetS and its components, and this may in part explain the variability of MetS incidence and prevalence in different race-ethnicity populations.

4. SUBCLINICAL CAROTID ATHEROSCLEROSIS AND RISK OF STROKE AND CARDIOVASCULAR DISEASE

Atherosclerosis is a physical manifestation of many of risk factors associated with stroke, such as hypertension, dyslipidemia, diabetes mellitus, obesity, that are all components of MetS. Carotid atherosclerosis accounts for a large percentage of both embolic and ischemic strokes. The development of noninvasive ultrasound methods capable of quantitatively evaluating atherosclerosis has improved our ability to design studies analyzing the natural history, progression, and determinants of carotid atherosclerosis, as well as to evaluate the effects of preventive measures. The most validated carotid traits currently used to evaluate CVD risk prediction are: carotid intima media thickness (cIMT), carotid plaque (CP) and its phenotypes, and carotid stiffness (STIFF).

Carotid Intima Media Thickness (cIMT) and Risk of Stroke and CVD

cIMT may be defined as a measurement of the thickness of the carotid artery walls. cIMT is increasingly used as a surrogate end point of vascular outcomes in clinical trials aimed at determining the success of interventions that lower risk factors for atherosclerosis and associated diseases such as stroke. [43] In a systematic meta-analysis, Lorenz et al. reviewed 8 observational studies conducted on a total of 37,197 subjects with carotid ultrasound data who were followed up for a mean of 5.5 years. For an absolute cIMT difference of 0.1 mm, the future risk of myocardial infarction (MI) increased by 10% to 15%, and the stroke risk increases by 13% to 18%. The risk for both end points decreased with the number of adjustments for risk factors. [44] Another study reviewed prospective epidemiological data in the general population, to determine the association of cIMT with cardiovascular risk. The main conclusions were that cIMT was an independent but relatively modest predictor of CHD, instead cIMT was an independent predictor for stroke, slightly better than for CHD as judged by the relative risks of both events. [45]

Despite these evidences, recently the enthusiasm has been decreased by the result of a recent meta-analysis conducted in 41 trials enrolling 18,307 participants. This study

demonstrated as the regression or slowed progression of cIMT, induced by cardiovascular drug therapies, do not reflect reduction in cardiovascular and cerebrovascular events. [46] In addition, variability in predicting risk of stroke varied across the cIMT measured in different carotid segments. For example, in 1,975 Framingham Offspring Study participants, investigators demonstrated that internal cIMT, but not common cIMT, was associated with higher prevalence of cerebral infarcts. [47] However, a study conducted in 5,056 patients enrolled in the Carotid Atherosclerosis Progression Study (CAPS) demonstrated that cIMT measured in common carotid artery, bifurcation, and internal carotid artery was highly predictive for stroke even after adjustment for age, sex, and vascular risk factors. Its predictive value was at least as high in younger subjects as in older subjects. [48] Interesting, recent findings from the PROG-IMT suggested that estimation of individual IMT progression may be more useful in predict CVD than the singular, one time point, IMT measurement. [49]

It is important to note that pathological changes of arterial medial hypertrophy or intimal thickening in the absence of atherosclerosis are not a real representation of atherosclerosis. However, because cIMT and atherosclerosis share common underlying mechanisms for both disease initiation and progression, cIMT may be better indicator or overall risk of stroke and CVD than an accurate measure of atherosclerosis per se. [50]

Carotid Plaque (CP) and Risk of Stroke and CVD

CP is a focal manifestation of atherosclerosis and is biologically and genetically different phenotype of atherosclerosis from cIMT. [51,52] Therefore, it is considered as an independent surrogate marker of vascular disease. Atherosclerotic plaques that are prone to rupture owing to their intrinsic composition such as a large lipid core, thin fibrous cap and intraplaque hemorrhage are associated with subsequent thromboembolic ischemic events. [53] Similar to cIMT, presence of stenotic atherosclerotic CP is a well-established risk factor for IS and CVD. [54,55]

In NOMAS, subclinical CP was a strong predictor of vascular outcomes. [56] In this study, we described the impact of CP stratified by traditional FRS categories on vascular outcomes, showing that about 30% of subjects in low and 42% in intermediate FRS category had CP. In addition, we found that CP with irregular surface increased the risk of ischemic stroke 3-fold. [57] The cumulative 5-year IS risk among individuals with an irregular plaque surface was over 8%, whereas those with regular plaque had <3%. These data suggested that plaque surface irregularity, even after adjusting for degree of stenosis and plaque thickness, is an independent predictor of stroke. These data from NOMAS were in agreement with the Rotterdam Study [58] where in an old population, presence of CP increased the risk of stroke and cerebral infarction about 1.5-fold, irrespective of plaque location.

Other studies conducted on NOMAS population showed that the calcified CP was an independent predictor of combined vascular events defined as ischemic stroke, MI or vascular death. [59] Moreover, we demonstrated that people with maximum carotid plaque thickness (MCPT) greater than 1.9 mm had a 2.8-fold increased risk of combined vascular events in comparison to the subjects without CP. Interesting, in this study, the amount of atherosclerosis overall was higher among whites and blacks than among Hispanics, but if CP was present, it had a significant impact on the vascular risk only among Hispanics.

Figure 1. B-Mode ultrasound measurement of plaque area in the carotid artery. Plaque area is measured by automated edge detection algorithm in defined segment of the carotid artery (the green box) with visualized atherosclerotic plaque (coded gray in the green box). Measured plaque area is 51.04 mm² (circulated in red in the view box located in the bottom right corner).

In fact, in fully adjusted models, the association between CP and vascular events was significant only among Hispanics, suggesting a role of race-ethnicity in the CP related risk of CVD.

Recently, some plaque's echographic parameters have shown to help detecting increased vascular risk. Currently, new evidence suggests that total plaque area is the strongest predictor of cardiovascular risk among the ultrasound phenotypes (plaque presence, thickness or cIMT). [60]

Taking together, these data support strong association between CP, stroke and CVD. However, the comparison of the results from various populations must be considered with caution. Differences in demographics and risk factor profiles across different study populations and use of different measurements of subclinical atherosclerosis may have contributed to varying plaque size and its associated risk of vascular events.

Arterial Stiffness (STIFF) and Risk of Stroke and CVD

STIFF is a measurement of the vessel wall's tendency to resist deformation by systolic BP during the cardiac cycle, and is considered a parameter of the arterial distensibility. [61] STIFF is greater among people with atherosclerosis, and is considered an early predictor of stroke and CVD. [62]

Functional properties of the arterial wall precede the clinical stage of atherosclerosis has been investigated in peripheral arteries (femoral and brachial) and in the aorta for many years by using different methodologies such as measurement of pulse wave velocity (PWV). Recent development of high-resolution and high-definition sonography has focused new investigations on the carotid arteries.

In a cohort of 79 end stage renal disease (ESRD) patients with a mean follow-up of 25 months, increased STIFF was associated with a 6.4-fold increased risk of CVD and all-cause mortality, independent of other prognostic factors such as diastolic BP and total cholesterol/HDL ratio. [63]

In a case-control study conducted in 267 stroke patients, carotid distensibility (inverse of STIFF) was significantly lower in stroke patients (0.353 mm, 95% CI: 0.326–0.379) than in control subjects (0.415 mm, 95% CI: 0.378–0.451) even after adjusting for BP values, diastolic carotid-diameter and height. Each 1 SD decreased in the carotid distensibility independently increased the likelihood of stroke by 167.0%. [64] Data from the SMART Study (Second Manifestations of ARterial disease) confirmed these findings. [65] In 420 participants with stenosis of > 50% in at least one of the internal carotid arteries, risk of ischemic stroke or TIA in the highest quartile (stiffest arteries) relative to the lowest quartile was 2.1 (95% CI, 1.1 to 4.1) after adjustment for age, sex, systolic BP, minimal diameter of the carotid artery, and degree of carotid artery stenosis. [66]

Several mechanisms may explain the association between increased STIFF and stroke. First, STIFF may favor the occurrence of cerebrovascular disease through an increase in central pulse pressure that influences arterial remodelling at the sites of both the extracranial and intracranial arteries, increasing the development of carotid artery stenosis, the likelihood of plaque ulceration and rupture as well as the incidence of cerebrovascular disease. Furthermore, STIFF may be associated with cerebral microvascular processes important in stroke pathogenesis. [62] In contrast, the Rotterdam Study [67] reported no association between carotid distensibility and CVD. Different populations, methods and analyses may explain the lack of replication of the study results. Nonetheless, as well as with the other carotid markers of atherosclerosis, the genetic component may play a pivotal role in STIFF. In addition, few studies investigated STIFF in different race-ethnicity populations. Recently, we reported race-ethnicity differences in STIFF and arterial diameter in NOMAS population. [68] We found that age was independently associated with greater carotid artery diameter among Hispanics but not among blacks or whites. Interesting, the association between age and STIFF was strongest among Hispanics, followed by blacks, and was not apparent among whites. These findings may offer a possible explanation for reported disparities in stroke morbidity and mortality among Hispanics compared to blacks and whites.

5. THE LINK BETWEEN COMPONENTS OF METABOLIC SYNDROME AND SUBCLINICAL CAROTID ATHEROSCLEROSIS

Each component of MetS has been significantly associated with earliest stages of atherosclerosis. However, in a recent study we demonstrated that traditional vascular risk factors explain only 21% of the variance in the total carotid plaque burden. [69] Therefore variation in subclinical carotid atherosclerosis is largely unexplained by known vascular risk

factors, suggesting that other unaccounted factors, both environment and genetic, play an important role in the determination of subclinical atherosclerotic.

Hypertension and Subclinical Carotid Atherosclerosis

Hypertension through many mechanisms such as impairment of the endothelium and inflammation increases risk of atherosclerosis and stroke. High BP levels along with age are the two major clinical determinants of cIMT and STIFF. In the Framingham Study, systolic BP was independently associated with carotid atherosclerosis in multivariate analysis. [70] The odds ratio for carotid stenosis for an increase of 10 mmHg in systolic BP was 1.22 (95% CI 1.10 to 1.37) in men and 1.21 (95% CI 1.12 to 1.31) in women. Hypertension had a significant effect on different phenotypes of atherosclerosis. A study conducted in 1,031 middle-aged (aged 40-60 years) demonstrated a significant difference in cIMT between the hypertensive and control subjects. Moreover, CP were found more frequently in the hypertensive patients than they were in their controls. Subjects with a long duration of hypertension (> 7 years) had higher prevalence of CP and greater cIMT than those with a short duration of hypertension. [71]

A different impact of hypertension on subclinical carotid atherosclerosis has been demonstrated among different race-ethnicities. In the ARIC among 15,587 middle-aged participants [72] higher hypertension categories were associated with cIMT in all ethnic and sex groups, in participants who did and did not use BP lowering medications. In participants who did not use medications, multiple linear regression models adjusted for diastolic BP and other risk factors found that systolic BP was positively associated with cIMT except in black men; diastolic BP was not related to cIMT in blacks and had a negative relation with cIMT in white men and a J-shaped relation with cIMT in white women.

Increased BP has been associated with STIFF in several studies. Recently, a link between hypertension, endothelial dysfunction and STIFF has been clearly demonstrated in hypertensive patients. [73]

However, only few studies have evaluated the association of hypertension with the occurrence of CP [71,74,75], and the mechanism linking hypertension with plaques remains poorly understood. An interesting study conducted in 1,008 Finns subjects [76] showed close relationship between hypertension, especially high systolic BP, and CP in carotid and femoral arteries. Of the subjects, 64% had CP in both carotid and femoral arteries. The subjects with high (160 mmHg) systolic BP had a three-fold risk for CP in both carotid and femoral arteries compared to those with lower systolic BP. In addition, male sex and long-lasting smoking were risk factors for the occurrence of carotid and femoral plaques.

Based on these evidences, several studies and ongoing clinical trials are currently aimed to evaluate the role of anti-hypertensive drugs in reducing carotid atherosclerosis.

Glucose Homeostasis and Subclinical Carotid Atherosclerosis

IR is a metabolic disorder characterized by diminished tissue sensitivity to insulin that originates from environmental factors, such as a sedentary lifestyle, central obesity, and genetic predisposition. [77] IR was found to accelerate atherosclerosis, inflammation, the

onset of DMT2, CVD, obesity, hypertension, chronic kidney disease, and dyslipidemia. [78] Although an association between DMT2 and subclinical atherosclerosis is evident, [79] however it is still unclear whether IR or FBG are independently associated with subclinical atherosclerosis among non-diabetic individuals. In 3,704 patients with DMT2, insulin sensitivity index but not hyperinsulinemia, was significantly associated with cIMT adjusting for age, sex, BMI, smoking, systolic BP, HDL and LDL cholesterol. [80] These data suggest that IR itself, but not hyperinsulinemia might be an underlying mechanism of subclinical atherosclerosis in patients with DMT2. The HOMA index of IR was also positively associated with CP in subjects without diabetes and CVD, with an odds ratio of 1.19. [81] Other studies confirmed these results demonstrating that both impaired FBG and impaired glucose tolerance patients have increased cIMT according to controls. [82]

The ARIC study reported differences on glucose homeostasis in predicting subclinical carotid atherosclerosis among different race-ethnicities. In overall population STIFF were higher with increasing concentrations of FBG. [83] This finding was consistent in both black and white examines and in both sexes. A 25% increase in FBG was associated in nondiabetic white men with a 5.8% increases in STIFF. In nondiabetic white women, the corresponding predicted changes were an increase of 16.6% in STIFF.

Insulin and higher blood glucose level may have a direct effect on the thickness and structure of the arterial wall. [24] *In vitro* studies have shown that insulin, in concentrations similar to those found in physiologic conditions, stimulates proliferation of cultured arterial smooth muscle cells from a number of species, including humans. [84] Endothelial cells cultured from large vessels are resistant to the actions of insulin, but hyperglycemia inhibits their proliferation. [84] These findings suggest that hyperglycemia and hyperinsulinemia may promote the development of atherosclerosis. However, the exact mechanisms are not fully understood.

Dyslipidemia and Subclinical Carotid Atherosclerosis

Dyslipidemia is considered the most prevalent and modifiable risk factor for atherosclerosis. Abnormalities of lipid metabolism lead to pathologic lipid accumulation in the vessel wall, proinflammatory effects in macrophages and chronic oxidative stress of endothelial cells, ultimately leading to the formation of atherosclerotic lesions. [85] As component of MetS is defined as: elevated triglycerides and apolipoprotein B (apoB)-containing lipoproteins, and low HDL. Serum lipoprotein (Lp) levels are significantly higher in patients with CP or cIMT than in controls without. [86] However, no significant relationship between Lp level and arterial endothelial function, smooth muscle response, or carotid wall thickness, even though other lipid risk factors like LDL and HDL ratio are correlated with abnormal arterial function and structure. [86]

The anti-atherogenic property of HDL has been documented in both clinical observations and laboratory settings. [87] Also the association between the ApoB and development of atherosclerosis evaluated as cIMT has been shown. [88] The Bogalusa Heart Study in a young cohort of 1,203 black and white subjects demonstrated that only non-HDL cholesterol, total cholesterol/HDL cholesterol, and ApoB emerged as significant correlates with cIMT, after adjusting for BMI, systolic BP, and other lipoprotein. [89]

Due to the complexity of lipid effects on atherosclerosis, we hypothesize that the ratio of lipid parameters, rather than single lipid parameters, was most associated with CP phenotypes. [90] In NOMAS, our results indicate a strong relation between blood lipid levels and presence of CP in a multi-ethnic population, suggesting that blood lipids likely influence the risk of CVD and particularly stroke due to their effects on atherosclerotic plaque formation. Elevated LDL was independently associated with CP. However, HDL and triglycerides were not significantly associated with plaque presence after controlling for other lipid parameters and vascular risk factors. An analysis of precursor proteins supported the strength of the LDL association. ApoB as the LDL precursor protein, was associated with an increased risk of plaque, whereas ApoA-I, the HDL precursor protein, was not. In fact, the lipid parameter most predictive of plaque presence was ApoB, and particularly the ratio ApoB:ApoA-I.

Other studies have also demonstrated no significant association between triglycerides and CP after controlling for other lipid parameters and vascular risk factors. [91,92]

Studies examining the effects of lipid-lowering treatments have provided strong evidence for an important role of lipids in the pathogenesis of carotid atherosclerosis. A meta-analysis suggested that the effect of statins on both risk of stroke and cIMT progression was closely associated with the reduction in LDL cholesterol. [93] Other recent studies demonstrated that short time treatment with lipid-lowering drugs may modify the CP morphology, [94] and reduce cIMT progression. [95]

Obesity and Subclinical Carotid Atherosclerosis

The association between obesity and CAD is well established. Obesity represents a chronic inflammatory status and adipocytes release either cytokines or an array of adipokines such as leptin, endowed with immunomodulating and systemic activities leading to atherosclerosis. Recently, the new concept of “obesity paradox” has been introduced. [96] Data from the PROFESS (Prevention Regimen for Effectively Avoiding Second Strokes Trial) [97] that reviewed 20,246 subjects stratified by their BMI and WC, found no statistically significant differences in the recurrence of stroke for lean (9.06%), overweight (8.82%), and obese (8.89%) groups over 2.5-year follow-up. In contrast, in NOMAS we stressed the importance to include WC to the traditional Framingham profile to better improve global vascular risk prediction. [98]

The role of obesity measured by BMI and WC in subclinical atherosclerosis is also controversial. The Cardiovascular Disease Prevention Campaign analyzed 840 female and 1,002 male participants divided into normal weight (BMI <25 kg/m²), overweight (BMI between 25 and 29.9 kg/m²) and obese (BMI >29.9 kg/m²). The results suggested that increasing body weight did not independently associate with carotid atherosclerosis. [99] Another study compared carotid atherosclerosis prevalence measured as cIMT in obese postmenopausal women with and without MetS. The results found that women with MetS had higher cIMT prevalence in respect to women without MetS. However, obesity per se was not associated to carotid atherosclerosis. [100] One of the reasons for a lack of the association may be that BMI may not truly reflect body fat distribution. WC, WHR, and skin-fold thickness have been shown to provide better information in addition to BMI. WC is considered a risk marker that reflects long-term deviations in several metabolic risk variables.

Visceral fat is more metabolically active and associated with inflammation, IR, and atherosclerosis. [101] WC was independently associated with CP and progress of cIMT in peritoneal dialysis patients. [102] In an observational study performed in 3,694 Korean patients with DMT2, cIMT and the frequency of CP were higher with increasing WC quartiles. [103] In contrast, a recent study demonstrated no statistical differences in STIFF between groups divided for WC values. [104]

Environmental and genetic factors may play an important role in the relationship between obesity and CVD. We evaluated the genetic and environmental contributions to cIMT and obesity in 440 subjects from 77 Caribbean Hispanic families. [105] Obesity phenotypes included BMI, WC, WHR, and skin-fold thickness. We found a substantial genetic contribution to cIMT, BMI, WC, and skin-fold thickness. Significant phenotypic correlations were found between cIMT at each segment and the 3 obesity phenotypes (BMI, WC, and skin-fold thickness). These results suggest that obesity and cIMT may share common genetic factors.

A debate regarding the obesity paradox and which measurement of obesity is more helpful in predicting atherosclerosis, stroke and CVD is still ongoing.

6. LINK BETWEEN METABOLIC SYNDROME AND SUBCLINICAL CAROTID ATHEROSCLEROSIS

A lively debate is currently ongoing as to whether MetS per se could impact carotid artery atherosclerosis. As we reviewed in the previous sections, all features of MetS are important risk factors for atherosclerosis, stroke and CVD. Several studies investigated the possible association between MetS and subclinical carotid atherosclerosis. In the ARIC [106], a large community-based cohort (more than 14,000 middle-aged adults), individuals who met the criteria for MetS had cIMT values 30 μm (95% CI, 10–50 μm) thicker than normal individuals. Subsequently, the Bruneck study [107] conducted in a cohort of 888 Italian subjects reported a significant association between MetS and CP progression, assessed as a change in CP score over 5 years of follow-up. In the same study, the plaque progression was also associated with increased risk of CVD. The Baltimore Longitudinal Study of Aging (BLSA) examined the relationship between MetS and cIMT and STIFF. [108] In 471 subjects free of clinical overt CVD at baseline, investigators found that MetS increases cIMT and STIFF across all age groups; and MetS exerts its effects on carotid structure and function independent of its individual components and other CVD risk factors. These findings were in agreement with the study in patients with the IR syndrome. [109] Recently in a cohort of 400 Chinese subjects, [110] MetS significantly increased cIMT and significantly impaired carotid elastic properties. Interesting, among the MetS components WC had a strong association with carotid atherosclerosis.

In NOMAS, we evaluated the relationship between MetS and subclinical atherosclerosis measured as CP presence. [111] We observed an independent association between the MetS and CP prevalence and MCPT. Further, CP prevalence and MCPT were significantly related to the number of MetS components found within each individual. Our study was also the first to show that MetS was related to carotid atherosclerosis in whites, blacks, Hispanics, men, and women in a single community-based elderly cohort. The relationship between MetS and

CP was somewhat stronger in men than in women, was weaker in white women, and particularly stronger in white and black men. The genetic mechanism may explain at least in part these results, especially among postmenopausal women in whom the atheroprotection of sex hormones is lost.

In NOMAS, we also demonstrated a significant association between MetS and STIFF. [112] This relationship was independent of sex and race-ethnicity. In addition, it was independent of presence of CP and cIMT, and lipid lowering and BP lowering agents that could affected artery wall function. Wider WC and elevated BP were MetS components most significantly associated with STIFF.

Despite these evidences, the debate regarding the role of MetS in subclinical carotid atherosclerosis continues. Recently, the Cardiovascular Risk in Young Finns Study [113] showed that despite all MetS definitions identified young adults with accelerated cIMT progression, MetS was not able to predict cIMT progression more than expected from the sum of its risk components.

Interesting sex-specific differences were reported for the relationship between MetS and carotid atherosclerosis. [114,115] In The Health 2000 Survey [115] MetS was an independent determinant of cIMT in both sexes. However, in women but not in men, MetS was associated with cIMT independently of its components suggesting that MetS provides additional information on a person's risk for early atherosclerosis beyond Framingham Risk Score in women but not in men. Other studies conducted in different race-ethnicity populations supported the associations between MetS and carotid atherosclerosis. [116,117]

Several mechanisms have been proposed for the link between MetS and subclinical carotid atherosclerosis. One well documented deleterious effect is the adverse role on the structural and functional properties of the vasculature such as thickness and stiffness. It is possible that a common pathogenic factor could underlie both the arterial structural changes and the alterations in the components that comprise MetS. In addition, glycation of matrix proteins, nitric oxide regulation and other molecular pathways have been implicated in endothelial damage mediated by MetS. [110]

Incidence of MetS is higher in the older population. [118] The age-adjusted prevalence of the MetS is estimated at 23.7% of the US population and increases to 43.5% of adults >60 years of age. Ageing renders the endothelium more susceptible to damage by insults. [119] Furthermore, viscoelastic properties, such as arterial wall thickening, increased elasticity, reduced compliance and increased STIFF, deteriorate with aging. [120] Therefore, when present, age is another important component in addition to the classical MetS components mediating the arterial damages and the risk for stroke and CVD. However, the exact underlying mechanism remains obscure.

Recently, other factors such as inflammation and oxidative stress have been involved in development of MetS. [110] Oxidative stress develops in hypertrophied adipocytes, which increase the synthesis of pro-inflammatory cytokines, while decreasing anti-inflammatory cytokines. Dysregulation of such adipocytokines is responsible for systemic inflammation and oxidative stress and contributes to the pathogenesis of the obesity-associated morbidity in MetS. [121] All of these mechanisms are linked with atherosclerosis and risk for CVD.

Further experimental and clinical studies are imperative to elucidate the real impact of MetS and its components on the subclinical carotid atherosclerosis.

Figure 2. Schematic diagram of the association between the MetS and its components, subclinical carotid atherosclerosis, stroke and CVD, and the interaction with oxidative stress, inflammation and genetic and environmental factors.

7. SUBCLINICAL CAROTID ATHEROSCLEROSIS AS POTENTIAL MARKER TO RISK-STRATIFY PEOPLE WITH METABOLIC SYNDROME

Because of the increased morbidity and mortality associated with MetS, along with the significant direct and indirect economic costs of the associated diseases, the health care system worldwide should urgently seek to initiate programs that identify subclinical disease and create aggressive treatment plans based on risk stratification. A major challenge associated with primary prevention of stroke just involves the early and accurate detection of subclinical carotid atherosclerosis in a population that is at risk but asymptomatic. Delay in identifying at risk populations may result in a missed opportunity to prevent a cardiovascular event, such as heart attack, stroke, or sudden death. Therefore, early detection of subclinical carotid atherosclerosis could help to prevent these vascular events and substantially reduce the levels of death and disability attributable to stroke. This goal may be furthered by developing, standardizing, validating, and disseminating noninvasive diagnostic techniques such as ultrasound methods for identification of stratified risk factors in the general population.

It has been reported that when subclinical disease develops, the traditional risk factors appear to have a smaller association with the subsequent development of clinical disease,

although the traditional risk factors are the primary determinants of subclinical disease. [122] Individuals with the MetS had a higher burden of subclinical carotid atherosclerosis, suggesting that markers of subclinical atherosclerosis are intermediate conditions before occurrence of stroke. From the data presented in the previous sections we may state that: 1. there is not a full consensus of MetS definition; 2. MetS is a risk factor for stroke and diabetes in variable manner, also depending on race-ethnicity; 3. each component of MetS is an important risk factors for stroke; 4. cIMT, CP, and STIFF are well validated markers of subclinical carotid atherosclerosis and prognostic factors for stroke and CVD; and 5. there is a strong link between subclinical carotid atherosclerosis traits and MetS, but variable link with each MetS component.

The fact that more components of MetS an individual possess, the greater is the risk of carotid atherosclerosis, suggests that the clustering of these components is important and that measuring carotid atherosclerotic burden may be a good indicator of risk of stroke. However, the variability of the criteria used to define MetS, and the different characteristics of the study populations make difficult evaluating the risk for stroke in patients with MetS generating a “detection gap”. The current “detection gap” between MetS patients at risk of stroke could be addressed using a combination of noninvasive surrogate markers of atherosclerosis, such as cIMT, CP, and STIFF, alongside traditional risk assessment (ie, Framingham scores).

In addition, repeated noninvasive measurement of surrogate markers may be useful in monitoring therapy in patients with a complex syndrome such as MetS. Prospective studies are need to establish the extent to which measurement of surrogate markers would add value when used in tandem with the traditional risk modification. Such studies should also help establish goals for initiating and monitoring therapies for stroke risk modification.

Moreover, the use of noninvasive surrogate markers in clinical trials may reduce the duration of the clinical trials, as well as the costs associated with conducting these trials. Just few clinical trials aimed to investigate the relationship between MetS and atherosclerosis have been performed and are ongoing. As a part of Hämeenlinna Metabolic Syndrome Research Program (HMS) (NCT01119404) surrogate indicators for atherosclerosis (biochemical markers for endothelial damage) are studied in 120 men with MetS, 120 men with CVD and 80 physically active controls and in different settings. A purpose of an ongoing clinical trial (Early Vascular Wall Changes by Magnetic Resonance Imaging (MRI) in Metabolic Syndrome Versus Metabolically Normal Pre-Menopausal Women: A Pilot Study; NCT01068535) is to identify novel markers of early atherosclerosis in young women by comparing the vascular permeability of blood vessel walls (of the carotid artery) in pre-menopausal women who have MetS versus healthy women.

In conclusion, patients with MetS have a disproportionately high risk of stroke morbidity and mortality. Individuals with MetS should be evaluated for subclinical cardiovascular disease, which is preferably detected by non-invasive ultrasound imaging markers of subclinical atherosclerosis. There is a strong evidence that MetS is linked to increased levels of vascular damage and early detection of vascular changes leading to overt vascular disease is an important step in early and effective prevention of stroke and CVD disease.

Chapter 50

CONJUGATED LINOLEIC ACIDS IN THE PREVENTION OF ISCHEMIC STROKE

Yuri Clement

Pharmacology Unit, Faculty of Medical Sciences,
The University of the West Indies, St. Augustine, Trinidad and Tobago

ABSTRACT

Epidemiological and case-control studies show that high dietary intake of conjugated linoleic acids (CLA) is associated with a reduced risk of ischemic stroke. Atherosclerosis, a major risk factor for ischemic stroke, is precipitated by immune processes which involve the interplay between monocytes/ macrophages, pro-inflammatory and chemotactic mediators at the site of vascular injury. Sparse clinical evidence showed that CLA supplementation had no effect on a surrogate measure of atherosclerosis. However, animal models show significant CLA isomer-specific regression and resolution in established atherosclerosis. Contrary to expectations, clinical trials found that linoleic acid supplementation actually increased plasma levels of pro-inflammatory markers, such as C-reactive protein, IL-6 and TNF- α . In contrast, *in vitro* studies show that linoleic acids inhibited the expression of pro-inflammatory mediators by modulating intracellular signaling pathways. The results of *in vitro* studies are inconclusive regarding the effect of linoleic acids on chemotactic mediators which are critical in the initiation and progression of atherosclerosis. In conclusion, observational evidence points to an inverse relationship between dietary CLA intake and the risk of stroke. However, the findings from clinical trials and laboratory studies are inconclusive and do not provide a clear understanding of the mechanisms underlying protection against ischemic stroke.

LIST OF ABBREVIATIONS

CLA	Conjugated linoleic acid
COX-1	Cyclooxygenase-1
COX-2	Cyclooxygenase-2
CRP	C reactive protein
HUVEC	Human umbilical vein endothelial cells
ICAM-1	Intracellular adhesion molecule-1
IL-6	Interleukin-6
iNOS	Inducible nitric oxide synthase
LDL	Low density lipoprotein
LPS	Lipopolysaccharide
MCP-1	Monocyte chemotactic protein-1
NF- κ B	Nuclear factor- κ b
NO	Nitric oxide
PDGF	Platelet-derived growth factor
PECAM-1	Platelet/endothelial cell adhesion molecule-1
sVCAM-1	Soluble vascular cell adhesion molecule-1
TIA	Transient ischemic attack
TNF- α	Tumor necrosis factor-alpha

INTRODUCTION

Ischemic stroke occurs when there is a sudden diminution in the blood supply to the brain. Endothelial dysfunction and atherosclerotic plaque formation play major roles in the narrowing of arteries supplying cerebral tissue. Observational studies suggest that linoleic acids may prevent the incidence of ischemic stroke. It has been hypothesized that these polyunsaturated fatty acids exert their effects by various mechanisms. In this paper the evidence regarding the probable role of conjugated linoleic acids in the prevention of ischemic stroke is presented based on the findings of observational studies, interventional studies in randomized, placebo-controlled clinical studies, *in vitro* cell cultures and animal models.

There is overwhelming clinical evidence which shows a direct correlation between saturated fatty acid intake and the incidence of cardiovascular and cerebrovascular diseases. Concurrently, there is much interest in the use of polyunsaturated fatty acids in the prevention of these conditions. Several studies have established an inverse relationship between polyunsaturated fatty acids intake, including linoleic acids, and the incidence of cardiovascular diseases. However, the impact of dietary intake of linoleic acids and the incidence of cerebrovascular events, including ischemic stroke, has been less extensively investigated.

OBSERVATIONAL EVIDENCE

One of the earliest case-control studies which attempted to link linoleic acid levels in the blood to the incidence of ischemic stroke was reported by Ricci and colleagues [1]. In this

study, the concentration of linoleic acid in red blood cell membranes was measured in 28 cases of recent ischemic events compared 56 age-matched controls. It was demonstrated that patients with ischemic stroke had significantly lower levels of linoleic acid compared with controls. Further evidence was provided by another case-control study which assessed linoleic acid content in subcutaneous adipose tissue in 10 recent cases of cerebral infarction and 10 matched controls [2]. These researchers showed that linoleic acid content in adipose tissue was 15% lower in ischemic stroke patients than in their matched controls.

A large prospective study screened and followed 7450 Japanese men and women between 40 and 85 years old for cardiovascular risk factors. After up to 9 years of follow-up, and 122 ischemic events, the study demonstrated that higher serum levels of linoleic acid was associated with a reduced risk of ischemic stroke [3]. It was postulated that this protection may be due to an effect of linoleic acid to lower blood pressure, reduce platelet aggregation and enhance erythrocyte deformation.

More recently, a study in Sweden followed 2313 middle-aged men for up to 32 years, with 412 cases of stroke or transient ischemic attacks during the period [4]. The investigators showed that a higher intake of linoleic acid protected against stroke and TIA. It was suggested that linoleic acid may be an appropriate long-term surrogate predictor for these cerebrovascular events.

EFFECTS ON MEDIATORS OF INFLAMMATION

Besides being a lipid disorder, it is now well established that atherosclerosis is a chronic inflammatory disease. Several pro-inflammatory mediators, known as cytokines, are pivotal in the initiation and maintenance of the inflammatory atherosclerotic state [5]. It is hypothesized that linoleic acid has its protective effect by attenuating the inflammatory responses which lead to the series of events leading to atherosclerotic plaque formation, and subsequently ischemic stroke.

Smedman and colleagues [6] conducted a randomized double-blinded placebo controlled study which included 53 men and women to determine whether conjugated linoleic acids supplementation affected markers of inflammation associated with the initiation and progression of atherosclerosis. The investigators showed that a 3-month supplementation with 4.2g/day (containing equimolar concentrations of *cis*-9, *trans*-11 CLA and *trans*-10, *cis*-12 CLA isomers) significantly increased serum levels of the pro-inflammatory marker C-reactive protein. However, supplementation had no effect on levels of other inflammatory markers such as tumor necrosis factor- α (TNF- α) or sVCAM-1.

Another randomized, double-blind, parallel study by Tholstrup and colleagues [7] included 75 postmenopausal women who were given conjugated linoleic mixture, *cis*-9, *trans*-11 CLA or olive oil (placebo) over a 16-week period. Pro-inflammatory markers were measured at baseline and at the end of the study to determine the effects of the intervention. It was shown that the linoleic acid mixture significantly increased markers of inflammation including CRP, IL-6 and TNF- α ; but had no effect on markers of endothelial reactivity such as ICAM-1, VCAM-1 and MCP-1. On the other hand, supplementation with *cis*-9, *trans*-11 CLA had similar effects on inflammatory markers as the olive oil control.

At the molecular level, tumor necrosis factor- α (TNF- α) is a potent pro-inflammatory cytokine which plays a pivotal role in augmenting the inflammatory response via the intracellular transcription factor NF- κ B. De-Lima-Salgado and colleagues [8] showed that linoleic acid inhibited lipopolysaccharide (LPS)-induced TNF- α production in a mouse monocyte cell line. Cheng and colleagues [9] also demonstrated that conjugated linoleic acid inhibited the LPS-induced inflammatory response in a macrophage cell line (RAW 264.7). The decrease in inflammatory response was due in part to the significant decrease in NF- κ B binding to promoter regions for inflammatory mediators. There was dose-dependent inhibition of the LPS-induced up-regulation of iNOS and COX-2 expression, with subsequent decreased production of NO and prostaglandin E2. These findings were corroborated by another *in vitro* study which showed that CLA inhibited the expression of COX-1 expression and production of prostaglandin E2 and thromboxane A2, by attenuating NF- κ B nuclear translocation.

ANTI-ATHEROSCLEROTIC EFFECT OF LINOLEIC ACIDS AND MOLECULAR PATHWAYS

The initiation and propagation of atherosclerosis is a complex inflammatory process commencing with vascular injury, exposure of endothelium accompanied by adhesion and migration of monocytes into the intima. Oxidized LDL-cholesterol play a major role as macrophages are transformed into foam cells. The concerted interactions between transcription factors, intracellular signaling pathways and numerous pro-inflammatory cytokines, adhesion molecules and chemotactic molecules are vital to the formation of atherosclerotic plaques. The cascade of inflammatory events leading to initiation and progression of atherosclerosis involves the expression several mediators including intracellular adhesion molecule-1 (ICAM-1), soluble vascular cell adhesion molecule-1 (sVCAM-1) and monocyte chemotactic protein-1 (MCP-1). MCP-1 has an important role in the migration, adhesion and infiltration of monocytes to the site of vascular injury and plays a key role in medial thickening at the site of atherosclerotic lesions. These events further promote atherosclerotic progression resulting in endothelial dysfunction and plaque formation [10].

To date, the clinical evidence is sparse regarding the hypothesis that CLA supplementation inhibits the initiation and progression of atherosclerosis. However, a randomized, double-blinded, placebo-controlled trial was conducted which involved 401 overweight or obese, but otherwise healthy subjects, given either 4g CLA (2.5g *cis*-9,*trans*-11 CLA, 0.6g *trans*-10,*cis*-12 CLA) or placebo for six months [11]. In this trial aortic pulse wave velocity was used as a surrogate measure for atherosclerosis, and biochemical assays were performed, including CRP to assess the effect of supplementation. At the end of the study the researchers found that pulse wave velocity did not change from baseline values in both groups, indicating that supplementation at this dose over the 6-month period had no effect on either initiation or progression of atherosclerosis. An additional finding was that *cis*-9, *trans*-12 conjugated linoleic acid had not effect of CRP levels; suggesting no anti-inflammatory effect.

On the other hand, several animal and *in vitro* studies were conducted to assess the effect of CLA and its isomers on established atherosclerosis, as well as to delineate the underlying molecular mechanisms involved. In an animal-based experiment by Kritchevsky and colleagues [12], rabbits were fed an atherogenic diet supplemented with CLA for 90 days. Compared to control animals, there was significant regression of established atherosclerosis in the arch and thoracic aorta by over 30% in CLA-treated animals. In yet another study, it was shown that apolipoprotein E knockout mice fed a high fat diet over 16 weeks, but given 1% ALA over the last 8 weeks, had not only regression of atherosclerotic plaque formation, but complete resolution compared with control animals [13]. It was also shown that there were significant decreases in aortic accumulation of macrophage and expression of macrophage scavenger receptor CD36 in CLA-fed animals.

Arbonés-Mainar and colleagues [14] conducted an *in vivo* study using apolipoprotein E knockout mice fed either *cis*-9, *trans*-11 CLA or *trans*-10, *cis*-12 CLA over 12 weeks. The investigators assessed atherosclerotic progression over the study period by measuring cross-sectional lesion and coverage area in the aortic root. It was demonstrated that *cis*-9, *trans*-11 CLA slowed the progression of atherosclerosis, whilst *trans*-10, *cis*-12 CLA accelerated progression.

In an *in vitro* experimental design using human macrophages incubated with *cis*-9, *trans*-11 CLA and linoleic acid for 48 hours there was significant increase in the expression of macrophage scavenger receptor CD36 [15]. This finding was in contrast to another *in vivo* study which showed otherwise [13]. A critical step in the initiation of atherosclerosis is the accumulation of lipids in macrophages, and Stachowska and colleagues [16] showed that *trans*-10, *cis*-12 CLA decreased lipid accumulation in macrophage and foam cell cultures.

Linoleic acid increased the platelet/endothelial cell adhesion molecule (PECAM)-1 and TNF- α -induced monocyte adhesion to human aortic endothelial cells [17]. These researchers also found that monocyte binding was enhanced by significant increase in E-selectin, vascular cell adhesion molecule (VCAM)-1, IL-8, MCP-1 and PGE2. In contrast, *cis*-9, *trans*-11 CLA reduced ICAM-1 and VCAM-1 expression on the surface of macrophages in culture [18]. It was also observed that this CLA isomer reduced the adhesion of macrophages to human umbilical vein endothelial cells (HUVEC). Similarly, using a HUVEC line, Lee and Vanden Heuvel [19] found that the less common *trans*-9, *trans*-11 isomer significantly reduced the expression of these atherogenic mediators, as well as E-selectin and P-selectin. These mediators are critically involved in the adhesion of monocytes to the site of vascular injury. Additionally, *trans*-9, *trans*-11 CLA decreased the adhesion of macrophages to the HUVEC cell line.

The complex pathways leading to arterial thickening, and subsequent occlusion, in atherosclerosis includes the incorporation of collagen into vascular intima-media. An *in vitro* experimental design using vascular smooth muscle cell lines from human aorta and coronary arteries showed that CLA isomers inhibited the platelet-derived growth factor (PDGF)-induced stimulation of collagen incorporation [20]. It was also shown that CLA inhibited the NF- κ B nuclear translocation, which could lead to the down-regulation of inflammatory pathways in the gene expression of chemokines and cytokines.

ANTITHROMBOTIC EFFECTS OF LINOLEIC ACIDS

The narrowing of the carotid artery by the formation of blood clots on ruptured plaques, which may break off and form emboli, also contribute to the dramatic reduction in cerebral blood supply and precipitate ischemic stroke. It has been hypothesized that linoleic acids may prevent cerebral infarction by modulating blood coagulation and fibrinolysis.

A clinical trial involving nine healthy young men, randomly assigned one of three diets enriched with stearic acid, oleic acid or linoleic acid, was conducted using a crossover design with 2-week intervention periods. There was at least 5 weeks washout between each intervention. In this study, by Hunter and colleagues [21], several factors for blood coagulation and fibrinolysis were measured at the start and end of each intervention period. The researchers found that fatty acid- enriched diets did not affect coagulability or fibrinolytic factors. However, it was shown that the linoleic-enriched diet significantly increased anti-aggregatory prostaglandin E1 binding to platelet membrane over the short-term.

In another clinical study [22], 17 healthy young women were randomly given either 3.9g/day conjugated linoleic acid supplement or sunflower oil (containing 72.6% linoleic acid, with no detectable CLA) for 63 days. The researchers found that short-term supplementation with CLA had no significant effect on platelet aggregation, prothrombin time, activated partial thromoplastin time or antithrombin III levels.

ANTIHYPERTENSIVE EFFECTS

Hypertension is a major risk factor for the development of ischemic stroke. Hypertension increases the likelihood of endothelial dysfunction and accelerates the events leading to atherosclerotic initiation and progression. The clinical evidence regarding the antihypertensive effects of linoleic acid is sparse. However, a randomized, placebo-controlled study involving 80 obese drug-naïve stage 1 hypertensive patients was conducted by Zhao and colleagues [23] to determine the effect of add-on conjugated linoleic acid with ramipril (37.5mg/day) over 8 weeks. The supplement, containing equimolar concentrations of *cis*-9, *trans*-11 and *trans*-10, *cis*-12 isomers, was shown to significantly enhance the blood pressure lowering effect of ramipril over the study period.

CONCLUSION

The clinical evidence provided by epidemiological and case-control studies suggest that a diet high in CLA may protect against ischemic stroke. Many pathophysiological factors are predictors of ischemic stroke, and inflammation is a major player in the etiology of atherosclerosis. Interventional clinical studies showed that CLA supplementation over the short term actually increased the expression of inflammatory markers, which should enhance molecular events leading to atherosclerosis. On the contrary, *in vitro* studies show that CLA inhibited inflammation in stimulated cell cultures.

The single clinical trial showed that CLA supplementation had no effect on atherosclerotic progression over six months. However, animal studies show isomer-specific

regression and complete resolution in established atherosclerosis. With regard to the involvement of monocytes/macrophages in the initiation of atherosclerosis, *in vitro* studies indicate that CLA modulates the expression of chemotactic mediators and adhesion molecules.

Observational evidence indicates that higher dietary intake of conjugated linoleic acids may reduce the risk of ischemic stroke. However, the findings from clinical trials and laboratory studies are mixed and do not clearly delineate mechanisms by which CLA may be acting to provide protection against ischemic stroke.

ABSTRACT

Despite advances in pharmacological and surgical interventions, patients' participation in therapeutic lifestyle modification after a minor stroke has been emphasized as the cornerstone of secondary stroke prevention. Therefore, minor stroke sequelae are not only a medical matter but also a self-management matter. Patients who have just experienced a minor stroke need to be equipped with self-management knowledge and skills to effectively participate in secondary prevention. This chapter presents a community initiative of an evidence-based self-management educational intervention complementing therapeutic intervention for secondary stroke prevention. Essential components for knowledge transfer from professional care providers to patients in community setting are discussed. Finally, this chapter makes an attempt to explore opportunities and challenges for sustaining community engagement in secondary stroke prevention for minor stroke patients.

INTRODUCTION

Transient ischaemic attack or minor stroke (herein ‘minor stroke’) continues to be one of the most under-estimated developmental stroke syndromes. It is a syndrome characterized by the sudden onset of discrete neurological symptoms that resolve completely within 24 hours without structural brain damage (Roger, Go, Lloyd-Jones, et al., 2011). Symptoms include numbness or weakness in the face, arm, or leg on one side of the body; slurred speech or difficulty in understanding speech; trouble seeing in one or both eyes; dizziness, loss of balance and coordination, and difficulty in walking (National Institute of Neurological Disorder and Stroke, 2011). In Hong Kong, the incidence of minor stroke from 1999 to 2007 is stable at around 8% (Chau et al., 2011). Over the 2009-2010 period there were 2,008 minor stroke patients discharged from hospitals in Hong Kong (Hospital Authority, 2011). Minor stroke has always been considered as a harbinger of ischaemic stroke (Rothwell, et al., 2006; American Heart Association, 2011). The Oxford Vascular Study found that after a minor stroke, the risk of subsequent ischaemic stroke was 8%-12% at seven days, 11%-15% at one month, and 17% at three months (Coull, et al., 2004). There is a 50% stroke risk in the first year and up to a 35% stroke risk 3-5 years after a minor stroke (Ho, 2002; Klein-Ritter and Wasserman, 2001). Minor stroke therefore is an urgent medical matter. The public in general, and minor stroke patients in particular, need to be educated to seek medical attention urgently for timely investigations and stroke prevention treatment.

Apart from uncontrollable risk factors such as age, ethnicity, having a family history of stroke, and previous minor strokes, there are two types of controllable risk factors: (1) medical factors, such as hypertension, atrial fibrillation, carotid artery disease, diabetes and hyperlipidaemia, and (2) lifestyle factors, such as physical inactivity, unhealthy diet, alcohol and tobacco use (National Stroke Association, 2011). Both types of controllable stroke risk factors can be managed: the former can be treated and the latter can be changed. For secondary stroke prevention to be effective, evidence from the National Stroke Association (2011) suggests that lifestyle modification is as equally important as pharmacological and surgical interventions for tight control of risk factors. Secondary stroke prevention can therefore be seen not only as a medical matter, but also a self-management matter since it requires modification of lifestyle habits, which heavily depend on the individual patient’s commitment and participation. However the patients’ participation in lifestyle modification is sub-optimal, especially after hospital discharge (Berra, 2010). The challenges for health care providers are to find ways to empower these patients to take on responsibility and to actively participate in self-management for secondary stroke prevention.

This chapter addresses (1) the paradigm shift needed in patient education for secondary stroke prevention; (2) the development of a community-based self-management education programme; (3) research evidence on the effectiveness of self-management educational interventions for patients with minor stroke; (4) the incorporation of research evidence into community practice and (5) ways of sustaining community engagement in secondary stroke prevention.

SELF-MANAGEMENT APPROACH IN SECONDARY STROKE PREVENTION: A PARADIGM SHIFT

It is commonly understood that treatment and care for patients does not end at hospital discharge. Very often, patients with chronic illness require longer follow-up care or post-discharge intervention that goes beyond the hospital boundary. Patients with minor stroke, due to the reversibility of neurological symptoms, tend to under-estimate the possibility of a subsequent stroke and its long-term impact on their health. Because of this under-estimation, patients with minor stroke warrant a tailor-made stroke prevention programme.

Table 1. Comparison of traditional patient education and self-management education.

	Traditional patient education	Self-management education
What is taught?	Disease-specific knowledge and information. Technical skills related to disease management such as blood pressure monitoring.	Knowledge and information to gain understanding related to disease management. Generic skills, such as problem-solving, goal setting and action planning, making choices, and resource utilization related to living with the disease.
What is the goal?	Compliance with treatment regimen with the behavioural changes taught to the patients to improve clinical outcome.	Increased self-efficacy to participate in day-to-day disease management for improved clinical outcome.
What is the underlying assumption?	Improved disease-specific knowledge creates behavioural change, which in turn produces better clinical outcomes.	Greater patient confidence in his/her capacity to make life-improving changes, which in turn improves clinical outcomes.
How is behaviour changed?	External motivation Health professional sets behavioural goals and actions for patient to follow.	Internal motivation Patients gain understanding and confidence to make informed choices for their own behavioural goal attainment.
What is the relationship between patient and health professionals?	Professionals are the experts and represent authority to tell patients what to do. Patients are the recipients.	Professionals are experts about the disease and patients are experts about their lives and what works for them. Patients and professionals share information and decision-making.
What is the teaching process?	Didactic. Professionals teach/provide information, patients listen and ask questions.	Small group interaction. Professionals as facilitators for peer group discussion, experience sharing and reflection.
Who is responsible for outcomes?	Professionals.	Shared responsibility between professionals and patients for solving problems and outcomes.

(Bodenheimer, et al., 2002)

A community-based project aimed at keeping minor stroke patients informed of the realities of their neurovascular changes and at involving them in taking responsibility to actively participate in prompt preventive measures to prevent/reduce the devastating consequences of a stroke was initiated in 2003. The key issue addressed was not whether minor stroke patients manage their illness, but *how* they manage.

This Project adopted an empowering partnering approach to care, in contrast to the traditional paternalistic approach. An empowering partnering approach encompasses two elements:

First, self-management education equips patients with knowledge about the disease as well as technical and problem-solving skills for day-to-day health monitoring and disease management. The theoretical framework underpinning the shift to self-management education is from self-efficacy theory (Bandura, 1977), which refers to the confidence level that a person needs to carry out a behaviour necessary to reach a desired outcome.

Through self-management education, patients gain understanding and confidence to accomplish new behaviours for goal attainment and subsequent desirable outcomes. Table 1 compares the differences between the traditional educational approach and the self-management approach (Bodenheimer, et al., 2002).

Second, a patient-professional partnership values the joint collaboration, where professionals bring knowledge and expertise about therapeutic goals and disease management options, while active and prepared patients bring expertise on their lives, their daily experiences and what will work for them (Funnell and Anderson, 2004).

A collaborative empowering partnering approach facilitates informed patients to accept shared responsibility with their health care providers for managing their health conditions and for solving daily health-related problems with informed choices, instead of passively following a health professional's prescription.

THE DEVELOPMENT OF A SELF-MANAGEMENT EDUCATIONAL PROGRAMME FOR MINOR STROKE PATIENTS

For an empowering and partnering approach to care, two important items in developing a self-management educational programme are the programme content and the teaching process.

The programme content must be able to prepare minor stroke patients with the necessary information to participate in secondary stroke prevention. Bodenheimer, et al., (2002) suggested that the information should include medical information about the nature of stroke, its clinical manifestations, warning signs, medical and therapeutic lifestyle interventions for secondary stroke prevention as well as social information, e.g., the availability of relevant local resources to support informational and self-management needs. The content of our specific Programme was based on the National Stroke Association guidelines (2011) on therapeutic lifestyle changes for secondary stroke prevention, with consideration for and adjustment of cultural-specific aspects for Hong Kong Chinese. Table 2 shows the self-management objectives and key components in the Programme.

The teaching process aimed to effectively empower patients to participate in secondary stroke prevention. In this Programme, the self-management educational intervention was

conducted in 2-hour small group sessions of 10 to 12 minor stroke patients, held once a week for 8 weeks in initial implementation and modified to 5 weeks in subsequent community practice.

Table 2. Self-management objectives and key components.

Self-management objectives	Key components
Discussion of experience of the minor stroke and self-management for secondary prevention.	Ice-breaking session for initiating a collaborative relationship among facilitators and participants. Participants sharing their individual experiences of and their feelings about the minor stroke. Participants explore the importance of self-management for secondary stroke prevention.
The facts about stroke: nature of stroke, its clinical manifestations, consequences, and risk factors.	Participants begin building knowledge about what happened to their body, why and how it happened, and what possible consequences could result from a stroke. Recognising the warning signs of stroke, the importance of reaching emergency medical facilities and action to call 999 (equivalent to 911 in USA) in the case of a suspected stroke. Recognising common stroke risk factors that are related to self-management for secondary prevention.
Current stroke management and secondary prevention.	Continuing to build knowledge of current therapeutic preventive intervention for minor stroke. Understanding of how self-management can complement therapeutic treatment is explored and discussed.
Understanding medication regime and importance of adherence.	Understanding therapeutic goals for tight risk factors control. Reinforce the importance of medication adherence and explore ways to enhance medication adherence. Identification of any difficulty in following the doctor's prescription, problems encountered and possible solutions.
Stroke prevention through adopting a healthy lifestyle.	Reinforce knowledge on behavioural risk factors. Recognising the participant's own stroke risk factors and risk behaviours in lifestyle. Verbalising individual goals and naming of actions required for preventing stroke recurrence. Exploring problem-solving to overcome hurdles.
Eating a healthy diet.	Building knowledge about the American Heart Association and National Stroke Association guidelines on healthy diets. Educating participants on how to make healthy choices when shopping for food or dining out. Exploring healthy cooking methods (attention paid to culturally relevant Chinese cooking). Exploring the benefits and cautions of eating herbal soup or medicated meals.
Establishing a regular exercise habit.	Suggesting participants to explore ways to initiate / enhance physical activities. Exploring individual preference for exercise pattern, length of exercise & pace of exercise. Correcting misconceptions about exercise. Coaching participants to practise self health monitoring for desirable exercise intensity and duration.
Putting thoughts into actions.	Consolidating goal setting and action plans for participating in lifestyle modification and self-management. Participants share personal insights gleaned from the experiential learning, and acknowledge their individual accomplishments.

(Sit, et al., 2007)

Experienced community care professionals (registered nurses in the initial implementation and registered social workers for subsequent implementations and networking) ran the

Programme as facilitators. The enhancement of self-efficacy was a key component guiding the self-management education process. Patients' self-efficacy beliefs can be enhanced through performance accomplishments, vicarious experience, verbal persuasion and physiological information all of which were part of the small group interaction (Lorig and Holman, 2003).

Performance Accomplishments

Learning and practising appropriate behaviours are considered to be the most potent efficacy-enhancing strategy—the experience of success (feeling of mastery) enhances self-efficacy, while regular failure decreases self-efficacy. In the Programme, facilitators acknowledge attempts and emphasize favorable behavioural changes made by the patients. Experience with behaviour and the attributions of success are an important source for the development of self-efficacy.

Vicarious Experience

Observing others' successful performance is another source of self-efficacy. They can serve as realistic positive role models and sources of inspiration by supplying information/tips about making a success of specific health behaviours. Some participants were sensitive to observed information when they themselves were inexperienced with the specific kind of behavioural change. They used observed indicators from which they could measure their own capabilities and then estimate their own possible success.

Verbal Persuasion

Verbal persuasion is the most often used source of self-efficacy. It is effective when it involves encouraging participants to attempt a little more than they are currently doing. Verbal attempts to convince people that they have the ability to perform a little more were frequently used by the facilitators to encourage participants in setting goals and devising an action plan. Also peers (other minor stroke patients in the group) can influence a participant who is reluctant to initiate a course of action (Gonzales, Goepfinger and Lorig, 1990). When participants were convinced of their abilities, they were more prone to persevere and not easily give up.

Interpretation of Physiological Information

Information about physiological parameters can also influence a participant's motivation and perseverance to initiate and continue specific self-management behaviours. In the Programme, participants were taught to take their pulse rate and to use the Borg Perceive Exertion Rating for assessing their own exercise tolerance. Such information could motivate patients to exercise at a desirable intensity and duration as a behavioural goal attainment.

Similarly, understanding high blood pressure as one of the stroke risk factors and the subsequent targeting of blood pressure range for tight control could reinforce the patients' understanding of the importance of and participation in daily self blood pressure monitoring, record keeping and medication adherence.

ESTABLISHING EVIDENCE-BASED PRACTICE IN COMMUNITY-BASED SECONDARY STROKE PREVENTION INITIATIVES FOR PATIENTS WITH MINOR STROKE

In order to establish evidence-based practice, a research study was conducted to examine the effectiveness of the Programme in (1) improvement in knowledge about stroke, (2) improvement in self-health monitoring practice, (3) behavioural change in adopting healthy lifestyle habits for stroke prevention, and (4) the reduction in stroke risk factors.

Method

The study employed a quasi-experimental design with participants being randomized by time slot to either a control group (CG) or an intervention group (IG). The CG received conventional medical follow-up while the IG received an eight-week community-based Secondary Stroke Prevention Programme in addition to the conventional medical follow-up. Outcome data were collected at three time points: before the intervention (T0), one week after (T1) and three months after (T2) the completion of intervention. Participants with the following characteristics were recruited: aged 18 or above, diagnosed to have had minor stroke by doctors, medically stable, independent in activities of daily living, cognitively intact, able to communicate in Cantonese, discharged from hospital and currently living in the community. Those with surgical intervention pending, with congenital cerebrovascular abnormalities or with stroke-like syndromes from other causes, were excluded. Data were obtained from face-to-face interviews using a structured questionnaire which included four sections: (a) sociodemographic profile, (b) lifestyle habits including smoking, drinking, self-health monitoring practice, exercise and dietary habits, (c) medication compliance, and (d) knowledge about stroke warning signs and risk factors. In addition, individual participants' physical parameters of stroke risk factors were screened, which included blood pressure, body mass index and fasting blood lipid (total cholesterol and triglyceride by *Accutrend^R* point-of-care device).

Results

The study recruited 190 participants. One hundred and forty seven completed the study, of whom 77 were from the intervention group and 70 from the control group. Twenty eight participants (25%) from the intervention group and 16 participants (19%) from the control group dropped out. Reasons for drop-out included: re-hospitalization, away from Hong Kong seeking medical treatment in mainland China, travelling overseas, and failure to contact. Also

participants in the intervention group who did not attain 80% attendance were counted as drop-outs. Comparison between completers and drop-outs showed no statistical significant difference in demographic characteristics.

Table 3. Demographic characteristics between participants in the intervention group and control group.

Demographic characteristics	Intervention group (n=107)	Control group (n=83)	P value ⁽¹⁾
	Frequency (%)	Frequency (%)

⁽²⁾ ADL denotes activity of daily living

(Sit, et al., 2007, p.277)

Key findings of the study are reported elsewhere (Sit, et al., 2007). Briefly, demographic characteristics of the participants showed that around 47% of them were aged below 65 years. This percentage indicates that stroke and ischaemic cerebrovascular events are not limited to older people. Over 50% of the participants had secondary school education or above. As shown in Table 3, demographic characteristics between participants in the intervention group and control group were compared and no statistical significance was found between the groups except that more participants in the IG lived alone than those in the CG ($p=0.013$). Regarding the presence of stroke risk factors, nearly 40% of the participants had hypertension. Around 32% of them were overweight, 27% and 18% had suboptimal blood triglyceride and total cholesterol level respectively. Regarding behavioural risk factors, only a small percentage were current smokers and alcohol drinkers, but a majority of the participants (63%) were physically inactive. Our findings are comparable with the local population statistics although the percentage of physically inactive people was higher (Centre for health Protection, 2011).

Intention-to-treat analysis was performed to examine the changes in outcome variables over the three-time points. Missing data were replaced with baseline values. Table 4 shows the outcome data at baseline, post one-week and three-month follow-up. Regarding knowledge level, participants in the IG showed significant improvements in correctly identified stroke warning signs ($p<0.001$) and emergency treatment seeking response in case of a suspected stroke ($p<0.001$), the latter had a 4-fold increase in correct responses. In behavioral risk factors, there was significant reduction in the intake of salted preserved food ($p=0.004$) and foods with high saturated fat content ($p=0.032$). The percentage of walking exercise participation in the IG group had stable performance over the 3 data collection time points ($p=0.98$), while the CG group participants had a 23.4% decrease ($p=0.021$). In self-management behavioural change, there was a significant improvement among IG participants in adherence to the medication regimen ($p<0.001$) and in self blood pressure monitoring ($p<0.001$). There was a 50% increase in IG participants who regularly monitored their own blood pressure.

Regarding physiological risk factors, a reduction in fasting triglyceride level was detected over the 3 months data collection period in both groups. The IG however showed a significant statistical reduction ($p<0.001$) where the CG did not. It was also noted that the BMI in the CG showed a statistically significant increase ($p=0.034$) while the IG had slight but not statistically significant decrease at the 3-month follow-up ($p=0.088$). It may be possible that participants in the IG made more appropriate lifestyle changes than the control group. No significant change was found among other physiological risk parameters, such as blood pressure, total cholesterol level and blood sugar level.

Table 4. Outcome data at baseline, post one-week and three-month follow-up.

TRANSLATING RESEARCH EVIDENCE INTO COMMUNITY PRACTICE IN SECONDARY STROKE PREVENTION FOR MINOR STROKE PATIENTS

That the community-based self-management educational intervention for secondary stroke prevention was effective in improving minor stroke participants' stroke knowledge, dietary and exercise lifestyle modification, self-management practices in blood pressure monitoring and adherence to a medication regimen is supported by the research evidence. Slight improvements in blood triglyceride level and BMI were noted, but the 3-month follow-up period might not be long enough to determine whether such improvements could eventually be able to meet the target values for tight risk factors control. The research experience and intervention protocol (educational programme contents and teaching process) had provided valuable groundwork and recommendations for subsequent large scale community implementation.

The followings highlight some essential experiences for knowledge transfer from professional care providers to patients in community-based educational programme.

Promoting Patients' uptake and Participation

Patient educational intervention is an important component of secondary stroke prevention but patients' uptake of and participation in such programmes are often below the recommended levels, especially after hospital discharge (Davies, et al., 2010). This problem prompted community practitioners to network with nurses in acute settings for programme promotion and making formal referral. Community practitioners' motivational communications via telephone calls were also found to be effective in increasing patients' uptake and participation in the community-based educational Programme. Our experience is in keeping with the conclusion from Davies, et al., (2010) systematic review.

Timing

It is important to capture the right time to inform and motivate minor stroke patients to participate in secondary stroke prevention. Educational intervention given soon after hospital discharge would be appropriate. After hospitalization, patients are away from professional care and face the challenges of managing their unpredictable health condition and making daily decisions on ways to maintain health. Introduction to knowledge through a community educational programme at this time may be compatible with the patients' learning needs, so they may then be more receptive to the information.

Knowledge and Skills Transfer

Self-health monitoring is an integral part of self-management for secondary stroke prevention. After attending the Programme, minor stroke participants' increased knowledge of hypertension as an important stroke risk factor was translated into an increase in their self

blood pressure monitoring practice. This reflects the importance of not only transferring knowledge, but also transferring self-management skills which included supervised hands-on practice during the Programme, self-practice at home, feedback and group sharing in subsequent sessions of the Programme.

Equally important is the transferring of problem-solving skills to enhance the patients' ability to deal with obstacles in initiating or maintaining a healthy lifestyle practice (Bodenheimer, et al., 2002). For example, advice on healthy eating is a culturally specific topic, so guidelines recommended by Western countries may not match the Cantonese eating style, food availability in local markets and affordability for individual patients. Therefore, to introduce dietary behavioural change, the Programme did not demand that participants follow specific menus but introduced them to making informed choices for deciding a stroke risk-reduction eating pattern that suited their own preferences and affordability. In Chinese culture, the dining table is not only for eating but also for socializing. Meals are served with shared dishes among a group of family members or friends. Problem-solving skills are deemed necessary for patients to deal with hurdles encountered when sharing eating with others, especially in the collective culture within the Chinese community.

Experiential Learning and Feedback

Self-management educational intervention emphasizes 'know-how' knowledge which is better learned through doing and experiencing (Price, 1993). The Programme engaged participants in short-term goal setting and action planning. The participants were asked to identify their own behavioural risk factors which they wanted to modify, addressing them one at a time, then to set short term behavioural goals and devise an action plan. In the week proceeding to the next session, participants had the opportunity to implement their action plan at home. The participants were asked to report back their home practice performance in the next group session. The facilitator gave feedback on the consistency/discrepancy between their plan and their reported actual behavior. Participants were given time to reflect on facilitating factors or barriers to behavioural change and to explore problem-solving strategies. The Programme affirmed the importance of experiential learning experience in self-management education and recognized the importance of individualized regimes developed from personal experiences and perceptions of what worked for them (Sit, et al., 2007)..

Peer Support

Heisler, et al., (2010) suggested that peers facing the same health behavioural or self management challenges could provide better reciprocal peer support for patients to manage their conditions. In the Programme, small group sessions with 10-12 participants in each group provided a platform for peer interaction and support. Each self-management education session opened with 15 minutes of experience sharing and closed with a word of commitment for goal attainment from each individual participant. The groups were conducted in a supportive and non-judgmental atmosphere to strengthen confidence and motivation. Experiences of successful goal attainment shared among peer participants provided sources of

inspiration to other participants by supplying information about the degree of difficulty of a specific behavioural change and strategies to overcome the difficulty. Also, through group interaction, participants themselves were able to realize how much they could offer and receive in the reciprocal support relationship. Experience from the Programme implementation suggested that an effective way to activate patients was to provide them the opportunity to both help and be helped through small group interaction.

SUSTAINING COMMUNITY ENGAGEMENT THROUGH TRANSDISCIPLINARY COLLABORATION

Since the initial implementation in 2003, the Programme has grown considerably with expanded networking with other health service providers. Similar to other chronic diseases, most stroke risks have behavioural factors. As discussed previously, therapeutic lifestyle modification is not a pure medical science, it involves behavioral and social sciences. Sustaining community engagement in secondary stroke prevention must draw together the strengths from health and social sectors with different knowledge and skills. This requires crossing the professional boundaries by combining the expertise of two or more professional fields to achieve a more holistic and sustainable community engagement in chronic disease management.

Transdisciplinary approach in Patient Empowerment

There are different types of cross-disciplinary approaches in practice for chronic disease management. The transdisciplinary team approach, which this Programme adopted, refers to professionals *working jointly using the same framework of care and sharing information* that draws together discipline-specific knowledge, concepts and intervention approaches to address mutually agreed aims and patient outcomes. It can be contrasted with the interdisciplinary approach where professionals *jointly work together* to address commonly agreed aims and patient outcomes; and the multidisciplinary team approach where professionals in different disciplines work *independently and sequentially* to address their own disciplinary-specific aims and patient outcomes (Gowdy, 2006).

A major challenge in the transdisciplinary approach to care is priority setting (Gibson, et al., 2002). A discipline-specific approach to priority setting has been found to be insufficient because it is not grounded in actual patients' needs and self-management problems as well as the social circumstances where self-management takes place. Therefore, in priority setting for self-management education, a synthesis of both health-specific and generic approaches to care is needed. For example, in programme planning, professionals of health and social disciplines join efforts and share expertise to develop self-management intervention on medication adherence. Health specific objectives include reinforcing the importance of medication compliance for secondary stroke prevention (e.g., the dos and don'ts for taking medication safely and correctly). Behavioural objectives include introducing generic problem-solving skills on *how to* enhance medication compliance relevant to an individual patient's work and life circumstances (e.g., how to minimize barriers and facilitate adherence, how to

communicate with their doctor when there is a health concern and how to find local community resources for professional advice). Through sharing of preliminary ideas among people from different disciplines, collaborative goals are mutually agreed and information delivery formats structured.

Another challenge in the transdisciplinary approach is interprofessional knowledge exchange. It is generally understood that putting professionals from different disciplines in the same classroom and having them teach together may not meet the challenges of cross-fertilization and knowledge exchange. In this project, interactive workshops and project team working groups have shown promising facilitation for information/knowledge exchange among community practitioners of different professional disciplines. By working collaboratively together and shared responsibility in patient outcomes, linkages between professionals were fostered. This could be expected to have resultant benefits for the transdisciplinary approach of care in community. Experience revealed from this Project highlighted knowledge and skills exchange among community practitioners from health and social disciplines. That is the synthesis of health related knowledge and motivational skills to bring about patients' behavioural change for lifestyle modification and taking up self-management responsibility for secondary stroke prevention.

Hospital-Community Interfacing

In chronic disease management, failure to meet self-management needs has long been a prime source of hospital readmission and patients/family carers' dissatisfaction. For minor stroke patients, the consequences could be more devastating because without adequately preparing and engaging these patients to self-manage for secondary stroke prevention, they could be at higher risk for another more serious cerebrovascular event. It has been generally expected that hospital health professionals are responsible for ensuring that patients are properly informed and adequately prepared to manage themselves for secondary stroke prevention. However, this may not be a realistic expectation in this era of short length of hospital stay, and therefore more responsibility for meeting self-management needs must now be shouldered in the community (Worth, et al., 2000).

To sustain community engagement in secondary stroke prevention, the need for more effective hospital-community interfacing has already been recognized by practitioners in health care and social work (Department of Health, 2008). Community practitioners, sometimes external to the mainstream health care sectors, have a key role in establishing conditions for the creation and dissemination of knowledge/information in self-management educational intervention and chronic disease management.

Four levels of service interfacing can be identified (Table 5). Linkage among service providers can be facilitated through initial networking (for example, information exchange on joint conference or health initiatives; shared newsletters and mailing lists) and then subsequently establishing formal linkage among service providers (for example, setting up formal chronic illness management platforms for communication among service providers from different sectors). Service interface at this level encompasses interfacing workflow, referral mechanisms, joint pre-discharge health talks and other post-discharge interfacing services and programmes.

Table 5. Levels of hospital-community service interfacing.

Level of interface	Components of interface		
	Resource	Governance and operation	Service
Network	Shared information	Nil	Nil
Linkage	Shared information	Overseeing committee	Single and multiple projects
Partnership	Shared information and staff	Shared governance	Current and new projects/ services
Integration	Shared information, staff and funding	Shared leadership and governance	Expanded and new services

(Chan, 2010)

Advancing the development to the hospital-community partnership level requires shared patient data (electronic database), interprofessional education, and shared responsibility of patient outcomes. However, Thomasgard, et al., (2004) identified challenges to service interfacing at partnership and integration levels, which are the existing differences inherited within the hospital and community care sector. These include different organizational goals and funding priorities, different approaches to protecting patient data and confidentiality, varying ethnocultural backgrounds among service providers from different sectors, and the diverse structure, size and resources associated with various fields of practice. Hence, in keeping with the paradigm shift in hospital-community service interfacing, a core function of professionals, administrators and policy makers is to build community capacity to enhance health care and chronic disease management.

CONCLUSION

The chapter presented a transdisciplinary community-based secondary stroke prevention project undertaken to promote the application of research findings that enhanced minor stroke patients' engagement in self-management for secondary stroke prevention. It highlighted the fact that patient education should go beyond the traditional medical oriented 'know-what' knowledge to include clinical and social relevant 'know-how' knowledge and self-management skills. This requires joint efforts and shared expertise among community practitioners from different disciplines to synthesize knowledge and skills for preparing and engaging patients' participation in self-management. To sustain community engagement for secondary stroke prevention, transdisciplinary care approach and hospital-community service interfacing as well as their related challenges were also discussed.

ABSTRACT

Behavioral and psychological symptoms are common in demented patients. They are a common cause for increased morbidity and mortality in these patients. These behaviors and symptoms contribute significantly to the direct and indirect costs of caring for patients with dementia. Antipsychotic medications have shown modest efficacy in the treatment of these behaviors. However, their use in demented patients has generated controversy due to the increasing recognition of the side effects especially cerebrovascular adverse events (CVAEs) and death. In this chapter we review the data on antipsychotic medications causing cerebrovascular adverse events (CVAEs) and death in elderly demented patients.

INTRODUCTION

Behavioral and psychological symptoms of dementia (BPSD) are defined as a heterogeneous range of psychological reactions, psychiatric symptoms, and behaviors, which may be disruptive, unsafe and impair the care of the patient in a given environment [1]. BPSD is common in demented patients and their prevalence tends to increase with the progression of the illness [2]. BPSD has a profound impact on both the patients and their caregivers and is associated with increased morbidity, cost of care and mortality [2]. Antipsychotic medications are commonly used to treat BPSD although they have modest efficacy and there is greater recognition of their side-effect profile [3-9].

The health regulatory agency in Canada was the first to raise concerns about the association of risperidone with cerebrovascular adverse events in clinical trials of elderly patients with dementia in 2002 [10]. This was followed by the US Food and Drug Administration (FDA) in 2003, publishing warnings about cerebrovascular adverse events and requiring changes in the prescribing information for risperidone [11]. In 2004, the European Agency for the Evaluation of Medicinal Products (currently known as the European Medicines Agency) issued public advice about the increased risk of cerebrovascular adverse events and mortality in elderly patients with dementia receiving olanzapine [12]. Again in 2004, the United Kingdom's Committee on Safety of Medicines (now known as the Commission on Human Medicines) advised prescribers that risperidone and olanzapine should not be used to treat BPSD because of clear evidence of an increased risk of stroke [13]. In 2005, the FDA published a warning that the treatment of behavioral disorders in elderly persons with dementia with atypical (second-generation) antipsychotics is associated with increased mortality [14]. There were a total of 17 placebo-controlled trials investigating olanzapine, aripiprazole, risperidone or quetiapine in elderly persons with dementia and concomitant behavioral disorders. Of the 17 trials, 15 showed numerical increases in mortality in the group receiving drug treatment as compared with the group receiving placebo. There were a total of 5106 patients that were enrolled in these studies and analyses have demonstrated an approximate 1.6 to 1.7-fold increase in mortality in these studies. Most of these deaths were found to be due to either heart-related events (eg, heart failure, sudden death) or infections (mostly pneumonia). The FDA asked the manufacturers of these drugs to include a Boxed Warning in their labeling to describe this risk and note that these drugs are not approved for the treatment of this indication. In addition to olanzapine, aripiprazole, risperidone and quetiapine, the atypical antipsychotic medications clozapine and ziprasidone and a combination product containing olanzapine and fluoxetine were included in the warnings. In 2008, the FDA extended the warning to also include conventional antipsychotic drugs [15].

In this chapter, we review the risk of CVAEs and death with antipsychotic medications when used to treat elderly patients with dementia. Using the current data we provide evidence based treatment recommendations for these behaviors. We organized the chapter into the risk of CVAEs followed by risk for death. Data for each of the events were further subdivided into randomized controlled trials, meta-analysis and other trials.

1. CEREBROVASCULAR ADVERSE EVENTS (CVAEs)

A. Randomized Controlled Trials

In the trial by Brodaty et al, elderly patients with a DSM-IV diagnosis of dementia of the Alzheimer's type, vascular dementia, or a combination of the 2 (i.e., mixed dementia) and significant aggressive behaviors were randomized to receive a flexible dose of either placebo or risperidone solution up to a maximum of 2 mg a day, for a period of 12 weeks [16]. These patients were between the ages of 79 and 89 years. Five patients in the risperidone group suffered a stroke and one had a transient ischemic attack (TIA). Five of these patients had vascular or mixed vascular and Alzheimer's type dementia. One patient had Alzheimer's type dementia. Five of the patients had a history of hypertension, 4 of these 6 patients had atrial fibrillation and 1 patient had diabetes mellitus.

In a 42-site, double-blind, placebo-controlled trial of outpatients with Alzheimer's disease and psychosis, aggression, or agitation, patients were randomly assigned to receive olanzapine (mean dose, 5.5 mg per day), quetiapine (mean dose, 56.5 mg per day), risperidone (mean dose, 1.0 mg per day), or placebo for up-to 36 weeks [5]. There were two cerebrovascular events or TIAs in the olanzapine group compared to one each in the quetiapine, risperidone and placebo groups, $P=0.92$.

Table 1. Summary of data from RCTs

Study	Conclusions
Brodaty et al. [16]	More patients in the risperidone group had CVAEs when compared to placebo group during the course of the trial.
Schneider et al. [5]	The risk of CVAEs was no greater in the drug treated group compared to the placebo group.

B. Pooled & meta-analyses and systematic reviews

In a review of the risperidone trials, De Deyn et al. found a total of 29 (3.9%) cerebrovascular adverse events with risperidone treated patients when compared to 7 (1.6%) in placebo treated patients [17]. Of these events, 61.8% were non-specific symptoms such as obtundation, dizziness, or weakness rather than strokes. Serious events including all events with lasting disability, hospitalization, or death as might be expected with stroke were seen in 12 (1.6%) of patients who received risperidone and 3 (0.7%) who received placebo. All patients were aged >85 years. Cerebrovascular adverse events were reported at an average of 30.7 days (range, 3 to 75 days) after beginning treatment with risperidone and 56.7 days (range, 24 to 82 days) for placebo. The incidence of cerebrovascular adverse events did not appear to be dose-dependent (i.e., in 3.7, 3.1, and 5.0% of patients receiving risperidone <0.75, 0.75 to <1.5, and ≥ 1.5 mg/day, respectively). A total of five patients died of a cerebrovascular adverse event, four (0.5%) in the risperidone-treated and one (0.2%) in the placebo-treated group.

In a post hoc analysis of pooled results from 11 randomized controlled trials of risperidone and olanzapine in elderly dementia subjects, Herrmann and Lanctot found an increased incidence of cerebrovascular adverse events when compared to placebo treated patients [18]. A total of 48 out of the 2187 (2.2%) drug treated patients experienced CVAEs when compared to 10 out of the 1190 (0.8%) placebo treated subjects. The combined relative risk was 2.7, 95% confidence interval, (CI), 1.4 to 5.3. Numerically more risperidone treated patients (33 out of 1009, 3.3%) experienced CVAEs when compared to olanzapine treated patients (15 out of 1178, 1.3%). The weighted relative risk was statistically significant for risperidone, 3.2, 95% CI, 1.4 to 7.2, $P=0.0004$, but not for olanzapine, 1.8, 95% CI 0.5 to 6.3, $P=0.36$. A reanalysis of the risperidone trials suggested that some of the increased incidence may have been accounted for by nonspecific events that were not strokes. A larger number of subjects in the risperidone trials were diagnosed with vascular and mixed dementias when compared to the olanzapine trials. This most likely accounted for the increased incidence of cerebrovascular adverse events in the risperidone trials when compared to the olanzapine trials.

In their meta-analysis, Schneider et al. included fifteen trials of 16 contrasts of atypical antipsychotics in the treatment of BPSD [19]. They included trials of aripiprazole (3), olanzapine (5), quetiapine (3) and risperidone (5). There were a total of 3,327 patients in the drug treated group compared to 1,728 in the placebo group. In all there were 63 CVAEs in the drug treated group when compared to 16 events in placebo treated group. There was an increased Odds Ratio (OR) by meta-analysis for CVAEs of 2.13 95% CI, 1.20 to 3.75, $P=0.009$, 1.9% versus 0.9% pooled. There was a significantly increased risk with risperidone $OR=3.43$, 95% CI, 1.60–7.32, $P=0.001$, 3.1% versus 1.0% pooled.

In the meta-analysis by Ballard et al, the investigators found that demented patients treated with risperidone and olanzapine had a higher incidence of cerebrovascular events (including stroke) than placebo treated patients [8]. Risperidone treated patients were significantly more likely to have serious adverse cerebrovascular events, OR, 3.64, 95% CI, 1.72 to 7.69, $P=0.0007$.¹⁵ The investigators concluded that the risk of stroke was similar for olanzapine.

In a review of three placebo-controlled trials of elderly patients with psychosis associated with Alzheimer's disease who were treated with aripiprazole, the investigators found that cerebrovascular adverse reactions (e.g., stroke, transient ischaemic attack), including fatalities occurred in 1.3% of aripiprazole-treated patients compared to 0.6% of placebo-treated patients [20]. Although this difference was not statistically significant, in one fixed-dose trial, there was a significant dose response relationship for cerebrovascular adverse reactions in patients treated with aripiprazole.

Sacchetti et al. completed a systematic review on quantitative reviews on stroke and antipsychotics [21]. The investigators found the incidence of cerebrovascular accidents (CVAs) to be between 2% to 4% in the drug treated group which was statistically significant. The investigators also found that preliminary data indicates that the highest risk of stroke was related to the first weeks of treatment and the rates were higher in older patients, cognitive impairment and vascular illness.

Table 2. Summary of data from pooled analyses, meta-analyses and systematic reviews

Study	Conclusions
De Deyn et al. [17]	Increased risk of CVAEs with risperidone compared to placebo.
Herrmann and Lanctot [18]	Increased risk of CVAEs with risperidone and olanzapine compared to placebo.
Schneider et al. [19]	- The risk of CVAEs in patients treated with the atypical antipsychotics was higher than placebo treated patients. - The risk of CVAEs was 3 times higher in risperidone treated patients compared to placebo treated patients.
Ballard and White [8]	- The risk of CVAEs in the risperidone treated patients is significantly higher than in the placebo treated patients. - Although the data for olanzapine was not made available, the risk of CVAEs appears similar to that of risperidone.
European Agency [20]	- The risk of CVAEs with aripiprazole was not statistically significant. - In one trial (a fixed-dose trial), there was a significant dose response relationship for CVAEs in patients treated with aripiprazole.
Sacchetti et al ²	- The incidence of CVAEs was found to be very low (2-4%). - The risk of CVAEs in the exposed group is about 1.3-2 times the non-exposed groups. - The risk of CVAEs in the typical and the atypical antipsychotic group is similar. - Highest risk of CVAEs is related to the first weeks of treatment. - Risk is higher in those who are older, with cognitive impairment and vascular illness.

C. Other Studies

In a retrospective population-based cohort Herrmann et al. found that the crude stroke rate per 1,000 person-years did not significantly differ among the patients treated with typical antipsychotics (5.7), risperidone (7.8), and olanzapine (5.7) [22]. Relative to typical antipsychotic users, the risk ratio for stroke was 1.1, 95% CI, 0.5 to 2.3 for olanzapine users and 1.4, 95% CI, 0.7 to 2.8 with risperidone users. Relative to olanzapine the users of risperidone were not at significantly increased risk of stroke-related hospital admission, adjusted risk ratio 1.3, 95% CI, 0.8 to 2.2. The investigators concluded that olanzapine and risperidone use was not associated with a statistically significant increased risk of stroke when compared to typical antipsychotic use.

Finkel et al. found that the use of risperidone and other antipsychotics were also not associated with a higher odds ratio (OR) of incident CVAEs when compared to either haloperidol or benzodiazepines [23]. The percentage of patients who had CVAEs in each group were; risperidone (0.86%), olanzapine (0.87%), quetiapine (0.56%), haloperidol (1.19%) and benzodiazepines (1.04%). When risperidone was used as the reference group the

odds ratio were: olanzapine, 1.05, 95% CI, 0.63 to 1.73; quetiapine, 0.66, 95% CI, 0.23 to 1.87; haloperidol, 1.91, 95% CI, 1.02 to 3.60; benzodiazepines, 1.97, 95% CI, 1.30 to 2.98. With benzodiazepines as the reference group, the OR of incident CVAEs for all antipsychotics as a class was 0.49, 95% CI, 0.35 to 0.69. In this study the significant predictors for CVAEs were prior cerebrovascular events and atrial fibrillation. The presence of hypertension was significant in the risperidone versus olanzapine comparison. Age, gender, indicators for atherosclerosis, diabetes, anti-clotting medications and vascular dementia were not significant predictors for CVAEs in this study.

Liperoti et al. in a case-control study on residents of nursing homes in 6 U.S. states, found the odds ratio of being hospitalized for CVAEs to be 0.87, 95% CI, 0.67 to 1.12 for risperidone users, 1.32, 95% CI, 0.83 to 2.11 for olanzapine users, 1.57, 95% CI, 0.65 to 3.82 for users of other atypical agents and 1.24, 95% CI, 0.95-1.63 for conventional antipsychotic users when compared to nonusers of antipsychotics [24]. The investigators also found that users of risperidone and conventional antipsychotics were not at increased risk of being hospitalized for CVAEs regardless of the presence of a previous history of stroke or TIA; adjusted OR, 1.49, 95% CI, 0.93 to 2.38 and 1.23, 95% CI, 0.68 to 2.23 respectively. However, among olanzapine users and users of other atypical agents a history of CVEs increased the risk of being hospitalized for CVEs, adjusted OR, 3.71, 95% CI, 1.55 to 8.84 and 4.63, 95% CI, 1.35 to 32.63 when compared to nonusers without such history.

In a cross sectional study, Formiga et al. included two hundred fourteen women and 106 men with dementia. The mean duration for follow-up was 20 months. 28 One hundred ninety-one patients (60%) had received treatment with neuroleptic drugs: 168 risperidone (53%), 10 haloperidol, six levomepromazine, four olanzapine, two quetiapine, and one thioridazine. The daily dose of risperidone ranged from 0.5 mg to 3 mg, and the mean time since the start of risperidone was 10.1 ± 12.0 months. Six patients experienced a new stroke during follow-up (mean 20 months): three of them in the risperidone group and three in the other group (two patients not taking neuroleptics and one on thioridazine); there were no significant differences ($P = 1.0$). Four patients experienced a TIA during follow-up (mean 18.4 months): one in the risperidone group and three in the other group (two not taking neuroleptics and one taking levomepromazine) ($P = 0.34$). Overall, 10 patients experienced some CVAE during follow-up (mean 19 months): four in the risperidone group and six in the other group (four not taking neuroleptics and one each on thioridazine and levomepromazine) ($P = 0.52$). The risk of strokes or TIAs in patients who had taken neuroleptics was no greater than those who had not taken any neuroleptics, 4 vs 2; $P = 0.90$ and 2 vs 2; $P = 0.90$.

Gill et al. in a population based retrospective cohort study followed 32,710 older adults (≥ 65 years) with dementia who were treated with antipsychotics [26]. Patients were observed until they were either admitted to hospital with ischemic stroke, stopped taking antipsychotics, died, or the study ended. After adjustment for confounding factors, participants receiving atypical antipsychotics showed no significant increase in risk of ischemic stroke compared with those receiving typical antipsychotics, adjusted hazard ratio 1.01, 95% CI, 0.81 to 1.2. The risk of stroke for patients receiving the individual drugs were as follows; risperidone, adjusted hazard ratio (HR) 1.04, 95% CI, 0.82 to 1.31, olanzapine 0.91, 95% CI, 0.62 to 1.32 and quetiapine 0.78, 95% CI, 0.38 to 1.57. This was not significantly different from that of patients receiving typical antipsychotics. The investigators found higher incidence rates of stroke in patients with atrial fibrillation who were prescribed atypical antipsychotics, adjusted HR 1.23, 95% CI, 0.70 to 2.02. Chronic users of atypical

antipsychotics were also not at increased risk of stroke compared with chronic users of typical antipsychotics, adjusted HR 0.89, 95% CI, 0.69 to 1.17.

In a 12 month controlled open-label study of nursing home patients, Moretti et al. included patients who were aged between 71 and 92 [27]. Patients were divided into two groups. One group received olanzapine 2.5 to 7.5 mg a day while the other group received typical neuroleptics (60 patients receiving promazine chloridrate 4%, up to 10 drops three times a day and 113 patients received haloperidol 0.2%, up to 10 drops three times a day). A total of 356 patients were included in this study and their mean age was 76.8 ± 4.01 years. In the two groups, the change from baseline on the Hachinski Ischemic Score were $+1.7 \pm 0.6$ and $+1.6 \pm 0.3$ respectively. The change Matthew's Stroke Scale were -5.4 ± 0.7 and -6.1 ± 0.7 respectively. These changes were not statistically.

Layton et al. compared the incidence rates for events reported as cerebrovascular accident (CVA) and transient ischaemic attack (TIA) during the first 180 days of treatment in patients prescribed atypical antipsychotics for dementia or other indications [28]. This analysis included 7684 risperidone treated patients, 1726 quetiapine treated patients and 8826 olanzapine treated patients. Among the risperidone, quetiapine and olanzapine cohorts, 23 (0.30%), 6 (0.35%) and 10 (0.11%) patients were reported to have had a CVA or TIA. Although age, sex and indication for prescription (dementia or other diagnoses) were identified as important confounding variables, age was being to be found to be the most important variable for developing a CVA or TIA. The crude rate ratios (RRs) for CVA or TIA for risperidone or quetiapine vs. olanzapine indicated an approximate threefold relative difference in rate during the first six months but after adjustment for age, sex and indication, the RRs were non-significant 1.2, 95% CI, 0.5 to 3.0 and 2.1, 95% CI, 0.6 to 7.7, respectively. For risperidone vs. quetiapine, crude and adjusted RRs were not significantly different, 0.84, 95% CI, 0.34 to 2.07, 0.73, 95% CI, 0.27 to 2.00. Of the three drugs, the time to event was shortest for risperidone, 58 days, range 0.5-168 days. The time was also shortest for risperidone and quetiapine users where the indication for use was dementia. The RR of CVA or TIA in patients prescribed risperidone for dementia when compared to other indications was 6.7, 95% CI, 2.4 to 18.9. The adjusted RRs for quetiapine, according to indication, could not be calculated due to missing data. There were no cases of CVA or TIA in the subgroup of demented patients who were prescribed olanzapine and hence the RRs and time to event curves based on indication could not be examined. The investigators concluded that dementia appeared to be an important risk factor for CVA or TIA, RR, 54.52, 95% CI, 19.41 to 153.16 and 16.91, 95% CI, 2.32 to 120.5 for the risperidone and quetiapine groups respectively.

Percudani et al. investigated the relationship between exposure to second-generation antipsychotics (SGAs) and the occurrence of cerebrovascular accidents in the elderly in a database review [29]. The analysis of cerebrovascular events in elderly subjects exposed to each individual SGA when compared to exposure to haloperidol, showed an increased risk only for risperidone, adjusted odds ratio, 1.43, 95% CI, 1.12 to 1.93.

Kolanowski et al. conducted an analysis of the claims data from a large health care insurer in the southeast region of the United States [30]. The investigators included only those cases that had at least one prescription claim for the 3-year period and the observation period was 45 days. In this study, the investigators found that the odds ratio (OR) for stroke was 0.98, 95% CI, 0.64 to 1.52 when the prescription was for typical antipsychotics. The OR was 1.18, 95% CI, 0.63 to 2.24 when the prescription was for atypical antipsychotics. The combined OR was 1.22, 95% CI, 0.55 to 2.68, $P = 0.91$.

In a prospective study of patients aged ≥ 65 years by Barnett et al, patients were observed until they were admitted to a hospital for a cerebrovascular event (CVE), stopped taking or switched antipsychotics, died or until the 18-month observation period ended [31]. After controlling for age, sex, race, marital status, veteran status, comorbid conditions, previous CVE, and prescription drug therapy, the risk of a CVE admission did not differ in those receiving FGA or SGA when compared to those not taking antipsychotics RR 1.20, 95% CI, 0.83 to 1.73. Patients with vascular dementia were found to have increased risk admission for CVE when compared to patients with Alzheimer dementia, RR, 1.14, 95% CI, 1.07 to 1.34. No difference in the risk of CVE admission was found in patients receiving either quetiapine, olanzapine, or risperidone, relative to haloperidol RR, 0.70, 95% CI, 0.30 to 1.65, 0.62, 95% CI, 0.25 to 1.53, 0.49, 95% CI, 0.21 to 1.12. Patients receiving quetiapine, olanzapine or risperidone, relative to haloperidol showed the RR to be 1.04, 95% CI, 0.33-3.91, 1.00, 95% CI, 0.30 to 3.35, 0.80, 95% CI, 0.26 to 2.43 for Alzheimer's dementia and 0.32, 95% CI, 0.07 to 1.46, 0.23, 95% CI, 0.04-1.38, 0.14, 95% CI, 0.02 to 1.68 for vascular dementia. The risk associated with vascular dementia patient relative to Alzheimer dementia patients was significant RR 1.39, 95% CI, 1.04 to 2.11. There was a decreased risk for CVE in vascular dementia patients receiving risperidone relative to those receiving haloperidol RR, 0.13, 95% CI, 0.03 to 0.63. No differences were seen in patients receiving either olanzapine or risperidone, compared to quetiapine RR, 0.84, 95% CI, 0.36 to 2.11, 0.73, 95% CI, 0.41 to 1.76 respectively. In this subgroup analysis, the RR for patients with Alzheimer's disease when compared to vascular dementia was 0.96, 95% CI, 0.39 to 2.32, 0.79, 95% CI, 0.36 to 1.71 respectively. The overall RR for vascular dementia relative to Alzheimer dementia was 1.08, 95% CI, 0.55 to 2.18.

In a study by Wang et al, patients who were 65 years old or older and filled a first recorded (index) prescription for an oral antipsychotic medication between January 1, 1994 to December 31, 2003 and had both parts A and B on all Pennsylvania Pharmaceutical Assistance Contract were included [32]. Atypical antipsychotic drugs aripiprazole, clozapine, olanzapine, quetiapine, risperidone and ziprasidone were included in this review. Other antipsychotics were considered as conventional drugs. By 30 days, adjusted hazards were not higher for conventional than atypical antipsychotics in developing cerebrovascular events, 1.08 95% CI, 0.99 to 1.18. By 60 days, conventional versus atypical antipsychotics was associated with a significantly increased hazard of developing cerebrovascular events, 1.10, 95% CI, 1.02 to 1.19. The hazards of developing cerebrovascular events were also significantly greater for conventional drugs than atypical antipsychotic use at 120 days 1.09, 95% CI, 1.02 to 1.16.

In a retrospective review of a Health Search Database, Sacchetti et al. included all elderly patients (≥ 65 years) who were prescribed an antipsychotic in monotherapy from January 2000 to June 2003 [33]. The comparison group was a cohort of patients who were not exposed to antipsychotics. The main outcome measure was the incidence of first-ever stroke during exposure to an antipsychotic. The crude incidence of stroke in subjects not exposed to antipsychotics was 12.0/1000 person-years, 95% CI, 11.5 to 12.5. The risk was significantly higher in those on butyrophenones, 47.1/1000, 95% CI 22.1 to 88.8, phenothiazines 72.7/1000, 95% CI, 43.3 to 107.7 and in the atypical antipsychotic group 47.4/1000; CI 23.4 to 86.5. Patients on substituted benzamides were also at higher risk, 25.0/1000, 95% CI, 12.0 to 34.1. The mean interval from first prescription to new-onset

stroke was 103.3 days, SD 112.7 in atypicals, 57.5, SD 22.2 in butyrophenones, 21.3, SD 18.8 in phenothiazines and 120.5, SD 119.6 in substituted benzamides. The risk of stroke was again higher for the group on phenothiazines, 5.79 times, 95% CI, 3.07 to 10.9, butyrophenones, 3.55, 95% CI, 1.56 to 8.07 and atypical antipsychotics, 2.46, 95% CI, 1.07 to 5.65 when compared with unexposed subjects. The group on substituted benzamides also had significantly higher risk, 2.2, 95% CI, 0.98 to 4.90. Phenothiazines also had a significantly higher risk, 2.34, 95% CI, 1.01 to 5.41 for stroke when compared with atypical antipsychotics. Older age, male sex, a Chronic Disease Score greater than 5, a diagnosis of Parkinson disease and the use of anticoagulants increased the risk of strokes. The diagnosis of dementia only had a weak effect on stroke risk and affective disorders were not associated with a risk for stroke.

In an electronic primary care records review by Douglas and Smeeth, the investigators identified 6790 eligible patients in the database with at least one prescription for an antipsychotic drug and a recorded incident stroke between January 1988 and the end of 2002 [34]. Of these 64% were women. The most commonly used typical antipsychotics were phenothiazines (5153 patients), and the most common atypical antipsychotic drug was risperidone (729 patients). The median age at first exposure to any antipsychotic drug was 80 years, while median age at the time of first recorded stroke was 81 years. The use of any antipsychotic drug was associated with a rate ratio for stroke of 1.73, 95% CI, 1.60 to 1.87. The rate ratio was 1.69, 95% CI, 1.55-1.84 for typical antipsychotics and 2.32, 95% CI, 1.73-3.10 for atypical antipsychotics. In patients receiving any antipsychotic drug, the rate ratios were 3.50, 95% CI, 2.97 to 4.12 for those with dementia and 1.41, 95% CI, 1.29 to 1.55 for those without dementia. In patients with dementia prescribed typical antipsychotics, the rate ratio for stroke was 3.26, 95% CI, 2.73 to 3.89. In patients with dementia treated with atypical antipsychotics, the rate ratio was 5.86, 95% CI, 3.01 to 11.38. Patients without dementia prescribed typical antipsychotics had a rate ratio of 1.40, 95% CI, 1.26 to 1.54 compared to 1.90, 95% CI, 1.36 to 2.65 to those prescribed atypical antipsychotics.

In a case-controlled analysis by Kleijer et al, a cohort of 26,157 community-dwelling patients (mean age 76 ± 9.7 years) with at least one antipsychotic prescription were included in the analysis [35]. Data from community pharmacies and hospital discharge records were utilized. Five hundred and eighteen cases of hospital admission for CVAE were identified. After adjustment baseline risk, current use of antipsychotics was associated with an increased risk of CVAE, adjusted OR, 1.6, 95% CI, 1.3 to 2.0. Patients who had a recent prescription (8 to 30 days ago) had a higher risk of CVAE compared with non-users, adjusted OR, 2.0, 95% CI, 1.3 to 3.3. Past use (>30 days ago) was not associated with an increased risk of CVAE, adjusted OR, 1.2, 95% CI, 0.9 to 1.6. There was a tenfold increase in risk of CVAE in the first week of use compared with controls, adjusted OR 9.9, 95% CI, 5.7 to 17.2. This risk decreased over time and was back on baseline level after 3 months of treatment, adjusted OR, 1.0, 95% CI, 0.7–1.3. There were no differences in risk between ischemic and haemorrhagic strokes. Exclusion of transient ischemic attacks (TIA's) in the analysis did not change the results. Cumulative exposure did not increase the risk for CVAE, ORs, 95% CI, 0.9 to 1.1. Users of conventional antipsychotics had an increased risk compared with users of atypical antipsychotics, OR 1.6, 95% CI 1.0 to 2.5; current users: OR 2.6, CI 1.3 to 5.0.

Table 3. Summary of data from other studies

Study	Conclusions
Herrmann et al. [22]	Olanzapine and risperidone use was not associated with a statistically significant increased risk of stroke compared with typical antipsychotic use.
Finkle et al. [23]	- Risperidone has similar risk of CVAEs compared to olanzapine, quetiapine and haloperidol. - The risk of CVAEs with antipsychotics is no greater than with benzodiazepines
Liperoti et al. [24]	- Users of risperidone and conventional antipsychotics had no increased risk of being hospitalized for CVAEs regardless of the presence of a previous history of stroke/TIA. - Olanzapine users and users of other atypical agents presenting with a history of CVEs were more likely to be hospitalized for CVEs compared to nonusers without such history
Formiga et al. [25]	No significant differences in CVAEs when comparing risperidone to haloperidol, levopromazine, olanzapine, quetiapine and thioridazine.
Gill et al. [26]	- No difference in the risk of ischemic CVAEs comparing atypical to typical antipsychotics. - The risk of ischemic CVAEs is similar for risperidone, olanzapine and quetiapine. - Atrial fibrillation may be a risk factor for ischemic CVAEs in patients treated with atypical antipsychotics.
Moretti et al. [27]	There is no statistically significant increase in risk of CVAEs with olanzapine compared to typical antipsychotics; promazine and haloperidol.
Layton et al. [28]	- The risk of CVAEs is similar for risperidone and quetiapine when compared to olanzapine. - Dementia appeared to be an important risk factor for CVAEs when treated with risperidone and quetiapine.
Percudani et al. [29]	The risk of CVAEs is similar in second generation antipsychotics compared to first generation antipsychotics except for risperidone where the risk may be higher.
Kolanowski et al. [30]	The risk of CVAEs was no greater in the typical or atypical antipsychotic group compared to placebo group.
Barnett et al. [31]	- There was no increase in the risk for CVAEs with FGA or SGA in the analysis stratified by type of dementia. - Overall, CVAE risk did not differ whether patients were receiving a FGA, SGA, or no antipsychotic therapy. - Patients with vascular dementia had an increased risk in hospitalization for CVAEs.
Wang et al. [32]	The risk of CVAEs is higher with conventional antipsychotics compared to atypical antipsychotics by 60 days and continues to 120 days.
Sachetti et al. [33]	- Phenothiazines had a significantly higher risk for CVAEs when compared with atypical antipsychotics. - Higher age, male sex, a Chronic Disease Score higher than 5, a diagnosis of Parkinson disease and the use of anti-coagulants increased the risk of CVAEs. - Dementia, <i>per se</i>, had only a weak effect on CVAEs and affective disorders were not associated to the risk.

Study	Conclusions
Douglas and Smeeth [34]	• All antipsychotics are associated with an increased risk of CVAEs. • The risk of CVAEs might be higher in patients receiving atypical antipsychotics than those receiving typical antipsychotics. • Patients with dementia appear to be at higher risk of CVAEs when treated with these medications.
Kleijer et al. [35]	• Current use of antipsychotics was associated with an increased risk of CVAE. • Recent prescription (8 to 30 days ago) had a higher risk of CVAE compared with non-users. • Past use (>30 days ago) was not associated with an increased risk of CVAE. • Cumulative exposure did not increase the risk for CVAE. • Users of conventional antipsychotics had an increased risk compared with users of atypical antipsychotics.
Chan et al. [36]	• The risk of developing CVAEs did not differ in typical or atypical antipsychotic user groups compared with non-user group. • Subgroup analyses of individual antipsychotic did not show a significant increase in risk of CVAEs.
Pratt, et al. [37]	• The incidence rate ratio (IRRs) for stroke was significantly raised in the first week following the initiation of a typical antipsychotic medication and returned to baseline level after 8 weeks of exposure. • No significant increase in the risk of stroke was found in any post-exposure period in patients taking atypical antipsychotics. • The risk of hospitalization for stroke was more than seven times greater in the week prior to initiating a typical antipsychotic but not an atypical antipsychotic medication. • Both groups had significantly increased risks of hospitalization for stroke up to 20 weeks prior to initiating therapy.

In a retrospective cohort study Chan et al. included patients aged 65 or above, who were diagnosed with Alzheimer's disease, vascular or mixed dementia and were admitted to an inpatient unit between 1st January 2000 to 30th June 2007 [36]. The patients were divided into three groups; typical antipsychotics, atypical antipsychotics and placebo groups. A total of 1089 patients were included in this study. Incidence rate of CVAE for the three groups were 44.6/1000, 32.7/1000 and 49.6/1000 person years respectively. The adjusted hazard ratio for the typical and atypical antipsychotic user groups were 0.964, 95% CI, 0.584 to 1.591 and 1.036, 95% CI, 0.350 to 3.066 when compared to placebo group. Subgroup analyses of individual antipsychotics did not show a significant increase in risk of CVAEs.

In a self-controlled case series using the Australian Government Department of Veterans' Affairs administrative claims dataset, Pratt et al. included 10638 patients aged ≥ 65 years with at least one hospitalization for stroke identified during the 4-year period from 1 January 2003 to 31 December 2006 [37]. The incidence rate ratio (IRRs) for stroke, after adjustment for age and calendar year, was significantly raised in the first week following the initiation of a typical antipsychotic medication, IRR, 2.25; 95% CI 1.32 to 3.83 and then returned to baseline levels after 8 weeks of exposure, IRR 0.82, 95%, 0.61 to 1.11. No significant increase in the risk of stroke was found in any post-exposure period in patients taking atypical antipsychotics, IRR, 1.46, 0.83 to 2.56. The risk of hospitalization for stroke was more than seven times greater in the week prior to initiating a typical antipsychotic compared with other

unexposed periods, IRR, 7.22, 95% CI, 5.30 to 9.84. This increased risk of hospitalization was not found in the week prior to initiating an atypical antipsychotic, IRR, 1.24, 95% CI, 0.68 to 2.28. Both groups had significantly increased risks of hospitalization for stroke up to 20 weeks prior to initiating therapy with antipsychotics; typical antipsychotics, IRR, 1.76, 95% CI, 1.25 to 2.49 and atypical antipsychotics, IRR, 1.39, 95% CI, 0.97 to 1.99.

RISK OF DEATH

A. Randomized placebo controlled trials

Brodaty et al. in their study found that 10 patients; 6 (3.6%) in the risperidone group and 4 (2.4%) in the placebo group died during the course of the trial [16]. The most common causes of death was pneumonia; 3 in the risperidone group and 1 in the placebo group and stroke, 2 in the risperidone group.

Schneider et al. found that in their double-blind, placebo-controlled trial of 421 outpatients with Alzheimer's disease and psychosis, aggression, or agitation there was 1 death in the olanzapine and risperidone groups whereas there were 3 deaths each in the quetiapine and the placebo groups [5]. The results were not statistically significant, $P = 0.58$.

In the study conducted by Ballard et al. in AD patients who resided in longterm care facilities in the United Kingdom were enrolled into a randomized, placebo-controlled, parallel, two-group treatment discontinuation trial [38]. Participants were randomly assigned to continue with their antipsychotic treatment; thioridazine, chlorpromazine, haloperidol, trifluoperazine, or risperidone for 12 months or to switch their medication to an oral placebo. The primary outcome was mortality at 12 months. Additional follow-up telephone assessment was done to establish whether each participant was still alive 24 months after the enrollment of the last participant, range 24 to 54 months. Causes of death were obtained from death certificates. Analysis was by intention to treat (ITT) and modified intention to treat (mITT). During the 12-month randomized, double-blind phase of the trial, comparisons between the patients who continued antipsychotic treatment and the placebo group during the showed that the cumulative probabilities of survival were 89.7%, 95% CI, 71.3% to 96.5% versus 97.1%, 95% CI, 80.9% to 99.6% in the patients who continued to take their allocated treatment for 12 months, 70.3%, 95% CI, 57.5% to 79.9% versus 76.6%, 95% CI, 64.2% to 85.2% in the patients who started their allocated treatment (mITT population), and 74.7%, 95% CI, 63.9% to 82.7% versus 79.3%, 95% CI, 68.8% to 86.6% in the ITT population. The Kaplan–Meier estimates show that during the extended follow up phase, the patients who continued antipsychotic treatment had significantly higher mortality compared with those who took placebo mITT population log rank $P = 0.03$, HR 0.58, 95% CI, 0.35 to 0.95; ITT population log rank $P = 0.02$, HR 0.58, 95% CI, 0.36–0.92. The difference in mortality was more pronounced after the first year. In the mITT population, the cumulative survival was 46% versus 71% between the continued treatment and placebo groups at 24 months, 30% versus 59% at 36 months, and 26% versus 53% at 42 months. The numerical differences at months 24, 36, and 42 were similar in the ITT population and the patients who took their medication for the first 12 months.

Table 1. Summary of data from RCTs

Author	Conclusions
Brodaty et al. [16]	More patients in the risperidone group died when compared to the placebo group during the trial.
Schneider et al. [5]	The risk of death in the drug treated group was similar to the placebo group.
Ballard et al. [38]	- The probability of survival in the antipsychotic group was less than the placebo group during the first 12 months. - The probability of survival decreases with continued treatment with drugs.

B. Meta-analysis and systematic review

In a meta-analysis by Schneider et al, the investigators evaluated 15 trials of 10 to 12 weeks duration which included 16 contrasts of atypical antipsychotic drugs with placebo met criteria; aripiprazole [n = 3], olanzapine [n = 5], quetiapine [n = 3], risperidone [n = 5] [39]. Death occurred more often among patients randomized to drugs 118 [3.5%] versus placebo 40 [2.3%]. The odds ratio (OR) by meta-analysis was 1.54, 95% CI, 1.06 to 2.23, P= 0.02; and risk difference was 0.01, 95% CI, 0.004 to 0.02, P= 0.01. Sensitivity analyses did not show evidence for differential risks for individual drugs, severity, sample selection, or diagnosis.

In the European Medicines Agency review discussed earlier, the rate of death in aripiprazole-treated patients was 3.5% compared to 1.7% in the placebo group [20]. Most of the deaths appeared to be either cardiovascular (e.g., heart failure, sudden death) or infectious (e.g., pneumonia) in nature.

Table 2. Summary of data from pooled analyses, meta-analyses and systematic reviews

Author	Conclusions
Schneider et al. [40]	Death occurred more often in the drug treated group compared to placebo group.
European Agency [20]	The rate of death is higher in the aripiprazole group compared to the placebo group.

C. Population based studies, retrospective analyses and other studies

In an observational study by Nasrallah et al, the investigators tracked the mortality over a 2-year period in patients aged ≥ 65 years who were receiving haloperidol (N=299) or the atypical antipsychotics risperidone or olanzapine (N= 1,254) [41]. Sixty-four patients in the haloperidol group (21.4%) and 61 patients in the atypical group (4.75%) died during the 2-year study period, P <0.00001.

In a prospective study by Raivio et al, elderly institutionalized patients with dementia were followed for up for two years [42]. Of these patients, 48.4% were prescribed antipsychotic medication: 37.4% received conventional neuroleptics and 11.0% received atypical antipsychotics. Of the users of atypical antipsychotics (risperidone, olanzapine),

32.1% died within 2 years. The respective figures for users of conventional neuroleptics were 45.3%, and for the nonusers, 49.6%. When comparing the users of any antipsychotic to the nonusers, the mortality was higher among the nonusers (72%) than among the users (58%), $P = 0.019$. Mortality was at first year among users 17% and among nonusers 27%, $P = 0.064$ and at two years 42% and 50%, respectively, $P = 0.24$. High number of medications and the use of physical restraints predicted higher mortality at two years; hazard ratio 1.12, 95% CI, 1.05 to 1.20, $P < 0.001$, 1.72, 95% CI, 1.04 to 2.83, $P = 0.03$ respectively. The use of atypical antipsychotic agents appeared to decrease the mortality risk and the effect of conventional antipsychotics was non-significant; hazard ratio 0.49, 95% CI, 0.24 to 0.99, $P = 0.047$, 0.68, 95% CI, 0.46 to 1.03, $P = 0.069$.

Barnett et al. evaluated VA patients admitted for pneumonia in fiscal year (FY) 2003 for exposure to typical and atypical antipsychotics and other neuropsychiatric drugs based on a prescription within 120 days preceding admission [43]. The odds of in-hospital mortality for patients admitted with pneumonia was higher for recent exposure to typical antipsychotics OR = 1.51, 95% CI, 1.04 to 2.19, $P = 0.03$ when compared to patients not receiving psychotropic medications. There was no significant difference in in-hospital mortality in patients exposed to atypical antipsychotics OR 1.20, 95% CI, 0.96 to 1.50, $P = 0.10$, tricyclic antidepressants OR 1.20, 95% CI, 0.44 to 1.55, $P = 0.15$, other antidepressants OR 1.07, 95% CI, 0.93 to 1.23, $P = 0.37$ or mood stabilizers OR 0.91, 95% CI, 0.73 to 1.14, $P = 0.41$.

In the study by Suh and Shah, the investigators measured the rate of mortality in patients with dementia, Alzheimer's disease (AD) and vascular/mixed dementia who were antipsychotics [44]. The 1-year mortality rate in dementia was 23.8%. The mortality rate in those who had not received antipsychotics (26.8%) was higher than that in those who had received antipsychotics (20.6%), unadjusted RR 1.168, 95% CI, 1.100 to 1.239. After adjusting for age and severity of dementia, the 1-year mortality remained higher in those who had not received antipsychotics adjusted model I: RR 1.202, 95% CI 1.107 to 1.324. When cerebrovascular disease, cardiovascular disease, hypertension, diabetes mellitus were added to the adjusted model I along with age and severity of dementia, the adjusted model II, RR was 1.211, 95% CI 1.107 to 1.324. When the total MMSE score was added to the adjusted model II, the relative risk was 1.244, 95% CI, 1.122 to 1.379 (adjusted model III). When both total scores of the Mini-mental State Examination (MMSE) and the Behavioral Pathology in Alzheimer's Disease Rating Scale (BEHAVE-AD) were added, the relative risk of mortality was 1.277, 95% CI 1.134–1.437 (adjusted model IV). Comparing those who had received both risperidone and haloperidol similar patterns were observed. The relative risks for all dementia, AD and vascular/mixed dementia in adjusted model IV, adjusted for age, severity of dementia, medical comorbidities, cognitive impairment measured by MMSE and BPSD measured by BEHAVE-AD were 1.225, 95% CI, 1.101 to 1.364, 1.226, 95% CI, 1.063–1.414 and 1.154, 95% CI, 0.959–1.389 respectively.

In an observational cohort study by Nonino et al, the investigators included a cohort of patients ≥ 65 years of age with BPSD who were treated with atypical antipsychotics and a cohort of demented patients who were not prescribed any atypical antipsychotics [45]. The measured outcomes were death by any cause and death by cerebrovascular accident at the end of the study with a median follow-up of one year. At one year, lower mortality rate was noted in the cohort not treated with antipsychotics, overall mortality rate 0.52 vs. 0.55/1000 years/person, rate ratio 0.95, 95% CI, 0.71 to 1.25; relative risk reduction 0.047, 95% CI, – 0.251 to 0.286. Mortality was higher among men, 0.74 vs. 0.46/1000 years/person, rate ratio

1.61, 95% CI, 1.33 to 1.94 and among patients with older age at entry, 0.33, 0.37, 0.61, 0.87 for ages 65 to 77, 78 to 82, 83 to 87 and 88 to 105 years respectively. Older age at entry, male gender, severe dementia and functional impairment were associated with a higher risk of death; hazard ratio 1.06, 95% CI, 1.04 to 1.08, $P < 0.001$, 2.20, 1.76 to 2.75, $P < 0.001$, 1.67, 95% CI, 1.32-2.11, $P < 0.001$, 1.81, 1.41-2.33, $P < 0.001$ respectively.

Gill et al. completed a population-based, retrospective cohort study in older adults with dementia [46]. The investigators ascertained the risk for death at 30, 60, 120, and 180 days after the initial dispensing of an antipsychotic medication. Two pairwise comparisons were made: atypical versus no antipsychotic use and conventional versus atypical antipsychotic use. New use of atypical antipsychotics was associated with a statistically significant increase in the risk for death at 30 days when compared with nonuse in both the community-dwelling cohort, adjusted hazard ratio, 1.31, 95% CI, 1.02 to 1.70; absolute risk difference, 0.2 percentage point and the long-term care cohort adjusted hazard ratio 1.55, 95% CI, 1.15 to 2.07; absolute risk difference, 1.2 percentage points. Excess risk seemed to persist to 180 days, although unequal rates of censoring over time may have affected these results. Conventional antipsychotics were associated with an even greater risk for death at 30 days. The adjusted hazard ratio was 1.55, 95% CI, 1.19 to 2.02 for the community-dwelling cohort and 1.26, 95% CI, 1.04 to 1.53 for the long-term care cohort adjusted risk difference for both groups, 1.1 percentage points. The risk persisted to 180 days, adjusted hazard ratio 1.23, 95% CI, 1.00 to 1.50; absolute risk difference, 2.6 percentage points and 1.27, 95% CI, 1.09 to 1.48; absolute risk difference, 2.2 percentage points, respectively.

In a population-based cohort study, Schneeweiss et al. assessed the short-term mortality in those older subjects who were prescribed conventional and atypical antipsychotic medications [47]. The investigators compared the 180-day all-cause mortality between residents taking conventional antipsychotic medications and those taking atypical antipsychotic medications. Within the first 180 days of use, 1822 patients (14.1%) in the conventional drug group died, compared with 2337 (9.6%) in the atypical drug group, mortality ratio 1.47, 95% CI, 1.39 to 1.56, adjusted mortality ratio, 1.32, 95% CI, 1.23 to 1.42. When compared to risperidone, haloperidol was associated with the greatest increase in mortality; mortality ratio 2.14, 95% CI, 1.86 to 2.45. Loxapine had the lowest mortality ratio, 1.29, 95% CI, 1.19 to 1.40. The greatest increase in mortality occurred among people taking higher than median doses of conventional antipsychotic medications, mortality ratio 1.67, 95% CI, 1.50 to 1.86 and during the first 40 days after the start of treatment, mortality ratio, 1.60, 95% CI, 1.42 to 1.80.

Liperoti et al. in a retrospective cohort study compared the risk of death associated with atypical and conventional antipsychotics in a population of nursing home residents with dementia [48]. The outcome measure was all-cause mortality at 6-months of follow-up. There were 1,907 deaths during the 6-month follow-up time; the rate of death was 44.6 per 100 person-years. The median follow-up time was 180 days for users of both atypical and conventional antipsychotics. Survival curves for users of atypical antipsychotics and users of conventional agents differed at the Mantel-Haenszel test ($P < 0.001$). The deaths started early at 8 to 10 days but were distributed throughout the entire follow-up time. The rate of death was increased for users of conventional antipsychotics, adjusted hazard ratio (HR), 1.26, 95% CI, 1.13 to 1.42. Relative to risperidone, a higher rate of death was documented for haloperidol HR, 1.31, 95% CI, 1.13 to 1.53, phenothiazines HR, 1.17, 95% CI, 1.00 to 1.38 and other conventional medications HR, 1.32, 95% CI, 0.99 to 1.80. No atypical

antipsychotic was associated with a differential risk relative to risperidone HR, clozapine 0.94, 95% CI, 0.40 to 1.79, olanzapine 0.95, 95% CI, 0.80 to 1.12, quetiapine 1.05, 95% CI, 0.80 to 1.39. The excess mortality associated with conventional antipsychotics was found only among those patients with dementia other than Alzheimer's disease HR, 1.31, 95% CI, 1.14 to 1.50.

Rossom et al. in a retrospective study compared four cohorts of exposed patients; haloperidol (n=2,217), olanzapine (n=3,384), quetiapine (n=4,277) and risperidone (n=8,249) and their risk of death. These cohorts consisted mainly of men aged ≥ 65 and older with a diagnosis of dementia [49]. Those subjects who received an antipsychotic medication were compared with randomly selected controls who did not receive antipsychotics. Cohorts who were exposed to haloperidol, olanzapine, quetiapine or risperidone had more comorbidities than their control cohorts. During the first 30 days, there was a significant increase in mortality in subgroups prescribed a daily dose of haloperidol greater than 1 mg, adjusted hazard ratio (HR) 3.2, 95% CI, 2.2 to 4.5, $P < 0.001$, olanzapine greater than 2.5 mg, HR 1.5, 95% CI, 1.1 to 2.0, $P = 0.01$, or risperidone greater than 1 mg, HR 1.6, 95% CI, 1.1 to 2.2, $P = 0.01$. There was no increase in mortality when the daily dose of quetiapine greater than 50 mg, HR 1.2, 95% CI, 0.7 to 1.8, $P = 0.50$ or less 50 mg, HR 0.7, 95% CI, 0.5 to 1.0, $P = 0.03$. After excluding inpatients and subjects discharged within 30 days and adjusting for any differences in baseline covariates, including time since previous discharge, prescriptions for haloperidol or olanzapine were still associated with greater risk of mortality during the initial 30-days of exposure, adjusted HR 2.3, 95% CI, 1.6 to 2.9, $P < 0.001$ and 1.4, 95% CI, 1.9, $P = 0.03$ respectively. For risperidone the adjusted HR was 1.2, 95% CI, 0.95 to 1.4, $P = 0.13$. Quetiapine was associated with significantly lower risk of mortality, adjusted HR 0.7, 95% CI, 0.5 to 0.97, $P = 0.03$. No antipsychotic was associated with greater mortality after the first 30 days.

In a retrospective population cohort study patients who were aged 60 years or older and newly prescribed antipsychotic drugs were included in the study [50]. They were categorized according to typical (n=156) or atypical (n=806) drug exposure. The mortality risks of users of typical or atypical antipsychotics compared to nonusers were evaluated with survival analysis, considering exposure to antipsychotic drugs as a time-dependent variable. At the end of two years, adjusted death rate was 3.7, 95% CI, 2.6 to 5.1, in those prescribed a typical antipsychotic drug with respect to those who were not prescribed any drug. The adjusted death rate for atypical antipsychotic drug was 2.5, 95% CI, 2.0 to 3.0. The adjusted death rate when comparing typical to atypical drugs were 1.5, 95% CI, 1.1 to 2.1 indicating a 50% increased risk of death. The risk was also higher in men, adjusted death rate, 1.5, 95% CI, 1.2 to 1.8. Death was also higher in those patients with comorbid cancer, adjusted death rate, 4.0, 95% CI, 2.8 to 5.8 and cardiovascular and cerebrovascular disease, adjusted death rate of 1.6, 95% CI, 1.2 to 2.1. Cancer and dementia were the most common causes of death in the typical antipsychotic cohort whereas dementia, respiratory infection, cancer, stroke and non-ischemic heart disease were the most common causes of death in the atypical antipsychotic group.

In a retrospective cohorts study Huybrechts et al, evaluated the risk of death in patients who were ≥ 65 years and had initiated treatment with psychotropics after admission to a nursing home in British Columbia between 1996 and 2006 [51]. Atypical antipsychotics were initiated in 1942 patients, conventional antipsychotics in 1902, antidepressants in 2169 and benzodiazepines in 4887 patients. Compared to users of atypical antipsychotics, users of

conventional antipsychotics and antidepressants had an increased risk of death; rate ratio [RR] 1.47, 95% CI, 1.14 to 1.91, 1.20, 95% CI 0.96 to 1.50 respectively. Users of benzodiazepines had a higher risk of death; RR 1.28, 95% CI 1.04 to 1.58 when compared with users of atypical antipsychotics. Cardiac arrest, ventricular arrhythmia and venous thromboembolism were uncommon events, with rates well below one per 100 person-years in all groups.

In a retrospective cohort study by Kales et al, the investigators compared the 180-day mortality rates in dementia patients aged ≥ 65 years who began outpatient treatment with an antipsychotic medications; risperidone, olanzapine, quetiapine, or haloperidol or valproic acid and its derivatives [52]. In adjusted intent-to-treat analyses, haloperidol was associated with the highest mortality rate (relative risk (RR), 1.54, 95% CI, 1.38 to 1.73) followed by risperidone (used as a reference), olanzapine (RR, 0.99, 95% CI, 0.89 to 1.10), valproic acid and its derivatives (RR, 0.91, 95% CI, 0.78 to 1.06), and quetiapine (RR, 0.73, 95% CI, 0.67 to 0.80). The mortality risk with haloperidol was highest in the first 30 days but decreased significantly and sharply thereafter. Among the other agents, mortality risk differences were most significant in the first 120 days and declined in the subsequent 60 days during follow-up.

In a population based cohort study Huybrechts et al. assessed the risks of mortality associated with use of individual antipsychotic drugs in elderly residents in nursing homes [53]. The investigators used the Cox proportional hazards models to compare the 180 day risks of all cause and cause specific mortality by individual drug with propensity score adjustment to control for potential confounders. The investigators found that compared with risperidone, users of haloperidol had an increased risk of mortality, hazard ratio (HR), 2.07, 95% CI, 1.89 to 2.26 and patients treated with quetiapine had a reduced risk, HR, 0.81, 95% CI, 0.75 to 0.88. The effect of haloperidol was strongest during the first 40 days of treatment, HR, 2.34, 95% CI, 2.11 to 2.60 and reduced to 1.32 (1.02 to 1.71) and 1.46 (1.07 to 2.00) after 40-79 and 80-180 days of treatment respectively. The corresponding rate ratios for quetiapine were 0.74 (0.66 to 0.82), 0.87 (0.75 to 1.01), and 0.91 (0.79 to 1.05). The investigators did not find evidence that the effect measure was modified by the presence of a recorded diagnosis of dementia or behavioral disturbances. Although no difference in overall mortality was observed for olanzapine, findings suggest a possibly lower risk of death from cerebrovascular diseases, HR, 0.88, 95% CI, 0.73 to 1.07. Given the relatively small number of patients treated with aripiprazole and ziprasidone the associations for cause specific mortality were imprecisely estimated. The investigators found a dose-response relation for all antipsychotic drugs except quetiapine. The dose effects were most pronounced for haloperidol, HR, 1.84 for high and 1.40 for medium dose, both compared with low dose and for risperidone (1.35 for high and 1.19 for medium dose). Almost half (49%) of deaths were recorded as caused by circulatory disorders, 10% by cerebrovascular diseases, and 15% by respiratory disorders.

Table 3. Summary of data from other studies

Author	Conclusions
Nasrallah et al. [41]	The risk of death was greater in the haloperidol treated group when compared to the risperidone and the olanzapine treated group.
Raivio et al. [42]	Users of antipsychotics had higher mortality when compared to nonusers.
Barnett et al. [43]	- The odds of in-hospital mortality for patients admitted with pneumonia was higher in those with a recent exposure to typical antipsychotics when compared to nonusers. - Patients exposed to atypical antipsychotics, tricyclic antidepressants, other antidepressants or mood stabilizers had no significant difference in in-hospital mortality.
Suh and Shah [44]	The rate of mortality was higher in the group not receiving any antipsychotic medication.
Nonino et al [45]	There was no increase in mortality in patients treated with atypical antipsychotics.
Gill et al. [46]	- Atypical antipsychotic use is associated with an increased risk for death compared with nonusers. - The risk for death may be greater with conventional antipsychotics than with atypical antipsychotics. - The risk of death is evident from 30 days to 180 days.
Schneeweiss et al. [47]	- The risk of death with conventional antipsychotic medications is comparable to and possibly greater than the risk of death associated with atypical antipsychotic medications. - The risk with typical antipsychotics is greater in doses above the median doses.
Leperoti et al. [48]	- Those receiving conventional agents, especially haloperidol, are at greater risk of death than those on atypical antipsychotics. - The excess mortality associated with the use of conventional antipsychotics is apparent within the initial 8 to 10 days of treatment and persists over 6 months. - The effect of conventional antipsychotics on increasing the risk of death relative to atypical medications seems to be clustered in residents with dementia other than Alzheimer's disease.
Rossum et al. [49]	Commonly prescribed doses of haloperidol, olanzapine, and risperidone, but not quetiapine, were associated with a short-term increase in mortality.
Musicco et al. [50]	- Adjusted death rate with typical antipsychotic drugs was higher than those who were not prescribed any drug or to those prescribed atypical antipsychotic drugs. - Adjusted death was higher in those patients with comorbid cancer and cardiovascular and cerebrovascular disease.
Huybrechts et al. [51]	Compared to users of atypical antipsychotics, users of conventional antipsychotics, antidepressants and benzodiazepines had a higher risk of death.

Author	Conclusions
Kales et al. [52]	• Haloperidol was associated with the highest mortality rate followed by risperidone, olanzapine, valproic acid and its derivatives and quetiapine. • The mortality risk with haloperidol was highest in the first 30 days but decreased significantly thereafter. • Among the other agents, mortality risk differences were most significant in the first 120 days and declined in the subsequent 60 days.
Huybrechts et al. [53]	• Compared with risperidone, users of haloperidol had an increased risk of mortality and patients treated with quetiapine had a reduced risk. • The effect of haloperidol was strongest during the first 40 days of treatment. • A dose-response relation was found for all antipsychotic drugs except quetiapine. • The effect was not modified by the presence of a diagnosis of dementia or behavioral disturbances.

Summary

Available data indicates that the risk of CVAEs is higher in elderly demented patients who are treated with antipsychotic medications. Although preliminary, existing data indicates that the risk is similar in both atypical and typical antipsychotics. No one particular drug has been found to be worse than the other in terms of CVAEs risks when used to treat elderly demented patients. A higher than median dose of a drug, older age, a diagnosis of dementia especially vascular dementia and comorbid atrial fibrillation have all been noted to be risk factors for CVAEs. The risk appears to be highest in the first week of treatment and remains elevated for about 20 months. Potential mechanisms by which antipsychotics can cause CVAEs include the development of orthostatic hypotension and tachycardia, most likely as a result of antagonism at alpha-adrenergic receptors [18] [54]. In individuals with cerebrovascular insufficiency CVAE can occur due to hypotension aggravating an already compromised cerebral perfusion, decreased cerebral perfusion due to rate-induced decrease in diastolic filling and cardiac output or tachycardia dislodging a thrombus in the patient with cardiac arrhythmia. Other mechanisms include hyperprolactinemia accelerating atherosclerosis and increasing the risk of CVAEs, sedation and resulting dehydration causing hemoconcentration and development of a thrombus. A venous thrombus which can embolize to the arterial circulation can also cause CVAEs especially in patients with cardiac arrhythmias [18] [54].

Current data indicates that risk of death with antipsychotics; atypicals and typicals is greater than when compared to the placebo treated group or the group that did not use these medications. Existing data for atypical versus typical antipsychotics indicate that the risk of death appears similar in both groups. No one drug appears safer than the other in terms of the risk of death. Older age, male gender, severe dementia and functional impairment are associated with a higher risk of death. The risk is highest in the first 30 days of prescription and appears to last for up-to 2 years. The mechanisms by which antipsychotic medications increase the risk of death is currently unclear. Most deaths are thought to be due to

cardiovascular events (mostly cardiac failure and arrhythmias) and infections (pneumonia) [48]. Antipsychotics are known to cause QTc prolongation with the highest estimated risk for thioridazine [47]. Increased risk of ischemic cerebrovascular events has been also linked to the use of atypical antipsychotics in patients with dementia [18] [27]. The comorbidities in these demented patients along with the use of these medications only add to this risk [18] [54].

CONCLUSION

Current evidence indicates that the use of antipsychotics increases the risk of CVAEs and deaths in elderly demented patients. Available data indicates that the risks are similar for both atypical and typical antipsychotics. The risk appears higher when used in older patients, in those patients with vascular dementia and atrial fibrillation and when higher than median doses of medications are used. The risk for CVAEs appears to be highest in the first week of treatment and tends to remain high for about 20 months. The risk of death is highest in the first 30 days of treatment and remains high for about 2 years. When using antipsychotics to treat BPSD, these risks should be considered in the context of the patient's age, diagnosis and comorbid conditions. Careful use of these medications with pragmatic evaluation of their risks and benefits will aid in the reduction of potential side-effects like CVAEs and death thereby preventing excessive morbidity and mortality.

ABSTRACT

Ultrasound is increasingly being used in the diagnosis, management and treatment of ischemic stroke. Linear array probes with frequencies of 5 to 10 MHz are used for extracranial studies, and sector or small hand-held 2 MHz probes for transcranial studies. Ultrasound is non-invasive, safe, painless, portable, quick, inexpensive, repeatable and accurate, but it requires adequate training; accreditation for physicians and laboratories are available. The extracranial arteries imaged include the common, internal and external carotid, vertebral, subclavian arteries bilaterally, and the brachiocephalic trunk. For transcranial studies, the ophthalmic artery, carotid siphon, terminal internal carotid, and proximal anterior, middle, posterior, basilar and intracranial vertebral arteries are evaluated. Brightness-(B) mode, intensity/power mode, colour-coded and Doppler mode are used; more recently, motion-(M)mode is also employed. Velocity parameters measured include the Peak Systolic, End-Diastolic and Mean velocities; resistivity parameters include the Gosling's Pulsatility Index and Pourcelot's Resistance Index. For safety, the Thermal Index cannot exceed 6, Mechanical Index 1.9, Spatial Peak Temporal Average Intensity 720 mW/cm². Ultrasound is used to evaluate extracranial and intracranial arterial stenosis, collateral flow as a result of severe stenosis/ occlusion, pulsatile neck masses, subclavian steal, carotid dissection, Takayasu disease, right-to-left shunting, embolisation, intra-operative monitoring during carotid endarterectomy or CABG and post-surgery/stent assessment of stenosis, as well as cerebrovascular reserve to predict stroke risk. It is also used therapeutically to enhance thrombolysis

(sonothrombolysis). Neurosonology provides an invaluable tool for the clinician in the management and prevention of ischemic stroke.

INTRODUCTION

Stroke is a leading cause of death and disability in many parts of the world. With the increasing numbers and aging of the population, as well as economic transition of less developed to more developed status, the number of people suffering a stroke will likely rise [1]. Approximately 54 – 85% of strokes are ischaemic in nature, with varying mechanisms including large artery atherosclerosis (includes atherothromobosis, artery-to-artery embolism and hypoperfusion), small artery occlusion, cardioembolism, other known causes, or unknown [2]. Large artery disease is largely amenable to detection by ultrasonography.

WHY ULTRASOUND

Ultrasonography is widely used in many fields of Medicine. It is increasingly being used in the diagnosis and management of ischaemic stroke. It is non-invasive, safe, painless, portable, quick, inexpensive, repeatable and reasonably accurate compared to other imaging modalities [3]. Computed tomographic angiography(CTA) and magnetic resonance angiography (MRA) should be considered as complementary rather than competing techniques. CTA requires the availability of a higher-end CT scanner, exposure to radiation and the injection of a contrast medium. MRA requires the availability of an MR scanner, is contraindicated in those with metallic implants or pacemakers, is a challenge in claustrophobic or very obese individuals or those who are haemodynamically unstable or on ventilatory support or restless, and has a long imaging time. The ‘gold standard’ remains catheter angiography with its antecedent risks of radiation, peri-procedural stroke, need for contrast injection, invasiveness and the need for expertise to perform it. None of these techniques is portable; they do not give real-time information; doing frequent, repeated studies and studies at the bedside is thus not possible or feasible. Cost-wise they are far more expensive than ultrasound, in terms of equipment purchase and maintenance and operating costs (Table 1).

Table 1. Comparison of neurovascular imaging methods

Features	Ultrasound	Computed Tomography Angiogram	Magnetic Resonance Angiogram	Catheter Angiography
Accuracy	++	+++	++	Gold standard
Low cost	+++	++	++	+
Speed	++	+++	++	+
Portability	++	0	0	0
Non-invasiveness	+++	+++	+++	0
Lack of radiation	+++	0	+++	0
Lack of contra-indications	+++	++	+	+
Low risk	+++	++	++	+

CLINICAL CEREBROVASCULAR ANATOMY AND PHYSIOLOGY

The brain receives blood supply containing oxygen and the only substrate it can use glucose via the carotid and vertebral arterial systems. The right common carotid artery (CCA) is a terminal branch of the brachiocephalic trunk (BCT, also called the innominate artery) which rises from the aortic arch in the thorax; the other terminal branch is the right subclavian artery (ScA). The left CCA and ScA arise directly and independently from the aortic arch. The diameter of the CCA is approximately 6mm.

The jugular vein on each side often lies superficial to its respective CCA, and can be identified by its easy compressibility, presence of valves, and flow in the opposite direction to the CCA. Each CCA ascends cephalically and bifurcates in the mid-neck usually at the level of the thyroid cartilage into the internal (ICA) and external (ECA) carotid arteries. The ICA then enters the petrous temporal bone.

The ICA can be differentiated from the ECA by a number of features – posterior-lateral location, dilatation at origin, larger diameter, low resistance flow pattern; the lack of branches is the key differentiating feature as is the Doppler waveform response to superficial temporal artery tapping (Table 2).

Table 2. Differentiating internal and external carotid arteries by ultrasonography

Feature	Internal Carotid Artery	External Carotid Artery
Location	Posterolateral	Anteromedial
Dilation at Origin	Yes	No
Diameter	Larger	Smaller
Branches in the neck	No	Yes
Flow pattern	Low resistance	High resistance
Response to superficial temporal artery tapping	No	Yes

The first branch of the ECA is usually the superior thyroid artery. The ECA's branches form many anastomoses with the ICA – superficial temporal artery with the supraorbital artery which is a branch of the ophthalmic artery (OA); facial artery with the dorsal nasal artery which is another branch of the OA.

The vertebral artery (VA) arises from the second part of the ScA and runs medially to enter the transverse process of the sixth vertebra. Each VA then ascends cephalically in the transverse foramen where it is easily and reliably identified, before it exits after traversing the second vertebra, winds round the transverse process of the atlas and enters the foramen magnum. The diameter of each VA is 2-3 mm, and may be dominant in one side, usually the right.

In its course through the petrous temporal bone, the ICA enters the cavernous sinus, runs anteriorly and then loops back, forming the carotid siphon (CS) where the OA is given off – OA flow is towards the eye. The ICA then again ascends cephalically, gives off the posterior communicating artery (PCoMA) which joins the posterior cerebral artery (PCA), and terminates as a bifurcation into the middle cerebral artery (MCA) and anterior cerebral artery (ACA).

The MCA runs laterally (M1 segment) before bifurcating or even trifurcating in the Sylvian fissure (M2 segments). The ACA runs medially (A1) and has a branch to the other ACA called the anterior communicating artery (ACommA), after which it becomes the A2 segment.

The VA in its intracranial portion gives off the posterior inferior cerebellar artery (PICA) and then joins the other VA at the ponto-medullary junction to form the basilar artery (BA). The BA runs cephalically over the pons and terminates at the midbrain-pons junction as the two PCAs. Each PCA runs laterally (P1 segment), is joined by the PCommA after which it becomes the P2 segment and then curves and runs posteriorly.

The Circle of Willis lies at the base of the brain and runs around the pituitary gland. It comprises the distal intracranial ICAs, M1s, A1s, ACommA, PCommAs and P1s, an important intracranial collateral circulation that is complete in only 50% of people.

Approximately 15% of the cardiac output, or about 750 ml/min of blood, is supplied to the adult brain, or 50-55 ml/100g brain/min – it is 75 ml/100g/min in grey matter and 45 ml/100g/min in white matter. Each CCA carries approximately 300-350 ml/min, each VA 50-100 ml/min. Cerebral autoregulation maintains blood flow within a constant range at systemic blood pressures between 50 and 150 mmHg. This is largely achieved by vasodilation and vasoconstriction of cerebral arterioles. The first response to reduced cerebral perfusion is cerebral vasodilation. In severe ischaemia, vasodilation is maximal; the inability for further dilation is referred to as a loss of cerebrovascular reserve, a portend of further ischaemic cell injury and stroke due to hypoperfusion.

IMAGING MODALITIES, INSTRUMENTATION AND INDICES

Extracranial Imaging usually studies the CCAs including the RCCA origin off the BCT, carotid bifurcations, proximal and mid-ICAs and ECAs, and proximal and vertebral portions of the VAs including their origins off the ScAs. The structural integrity and anatomy of the vessels, intimamedial thickness (IMT), plaques, intimal flaps, and luminal thrombi are imaged using B- (= Brightness) mode. Intensity-, also called power-, mode imaging detects the presence of flow. Colour-coded Doppler imaging gives information of the direction of flow and a qualitative estimate of velocities of moving red blood cells. Doppler imaging transforms frequency shifts to velocities; pulse-wave Doppler is preferred over continuous-wave Doppler as specific depths can be targeted and interrogated. The combination of B-mode and Doppler is called Duplex Imaging; the addition of colour-coding makes it Triplex Imaging.

Due to poor resolution, B-mode is used in Transcranial Imaging (TCI) only to locate the midbrain after which Triplex Imaging is performed to locate arteries and determine flow direction and velocities. Intensity-, also called power-, mode imaging is also used. Transcranial Doppler (TCD) is a blind technique using only Doppler to detect arteries and determine flow direction and velocity at various depths. B-mode has been used to detect large intracranial hemorrhages and hydrocephalus, but CT and MRI are far superior techniques. TCD has also been used to detect high intensity transient signal (HITs) presumed to be due to microemboli and to assess intracranial flow changes after manoeuvres. M- (=Motion) mode is a new TCD technique that allows multiple depths to be studied simultaneously. In addition to

detecting areas of stenosis, TCI and TCD also detect the intracranial effects of extracranial disease including collateral flow, and TCD is used to detect embolisation from a more proximal source, and assessment of cerebrovascular reserve. They are also used therapeutically to enhance thrombolysis (sonothrombolysis).

Doppler frequencies of 5 to 10 MHz are used for extracranial imaging as the arteries are superficial; linear array probes are used, with higher frequencies allowing better spatial resolution. Transcranial imaging requires 2 to 2.5 MHz frequencies due to the attenuation by the bones of the skull and deeper location of structures to be imaged; sector or small hand-held probes are used. Duplex and Triplex machines are large and may be portable if wheel-mounted; laptop and even hand-held versions are now available. Pure TCD machines are smaller, and may even be small enough to be carried in a back-pack.

Velocity parameters measured include the peak systolic (PSV), end-diastolic (EDV) and mean (MV) $[= EDV + (PSV-EDV)/3]$ velocities. Resistivity parameters include the Gosling's Pulsatility Index $[= (PSV-EDV)/MV]$ and Pourcelot's Resistance Index (RI) $[= (PSV-EDV)/PSV]$. A number of factors affect velocities, including age, heart rate, blood pressure, haematocrit, fever, hypoglycemia, and hypercarbia.

SAFETY

Ultrasound may potentially harm body tissues due to the high intensity of ultrasound energy used and prolonged duration of insonation, causing thermal (heating) and non-thermal (cavitation, streaming) effects. Heating affects the integrity of tissues and proteins, and the rate and equilibrium of chemical reactions. The Thermal Index (TI) is the regulated matrix; the TI in Soft tissue (TIS) and TI in the Cranium (TIC) are the sub-indices of relevance to neurosonology. Cavitation is due to the expansion and contraction (stable cavitation), and the more dangerous collapse (transient cavitation) of gas bubbles during the oscillatory cycle; pressure, force, torque and streaming are due to the force of pressures. The primary regulated metric is the Mechanical Index (MI). Currently the US Food and Drug Administration stipulates that diagnostic ultrasound scanners cannot exceed a TI of 6 and an MI of 1.9; the Spatial Peak Temporal Average Intensity $I(SPTA)$ cannot exceed 720 mW/cm². For ophthalmic imaging, $I(SPTA)$ cannot exceed 17 mW/cm² while MI should be less than 0.23. At all times, the As Low As Reasonably Achievable (ALARA) principle should be used – the lowest energy intensity and shortest study duration that allows a reasonable study [4].

PERFORMING AN EXTRACRANIAL TRIPLEX EXAMINATION

The patient is placed supine with the head partially laterally rotated away from the side to be examined. The gel-covered probe in B-mode is gently placed transversely in the mid-neck over the sternomastoid muscle and the CCA imaged as a 1cm diameter pulsatile structure with a dark (=anechoic) lumen and bright (=echoic) wall (Figure 1). It is then traced proximally to the base of the neck; on the right side, the BCT is also imaged. The probe is then moved cephalically and the carotid bifurcation identified as two circular pulsatile structures (Figure 2). The ICA and ECA are differentiated and the ICA traced as distally as

possible. The probe is then placed at the bifurcation and rotated so as to image the bifurcation in the longitudinal plane (Figure 3). The distal CCA, proximal ICA and ECA are identified. The vessels are traced proximally and distally. The intimal-media thickness (IMT) is measured, usually in the far wall of the distal CCA (Figure 4). Then the intensity/power mode is turned on to confirm flow in all segments of the arteries (Figure 5). The colour-coded Doppler is then used to confirm flow direction and identify areas of turbulence which may represent sites of stenosis (Figure 6). Finally, in the Triplex mode, the Doppler is used with a narrow sample volume placed in the centre of the artery at specific points as well as areas of turbulence, and an insonation angle steered along the direction of flow, not to be more than 60 degrees (Figure 7). The highest velocities are recorded in the proximal and distal CCA; origin, bulb and as distally in the ICA as possible; proximal ECA.

Figure 1. Right common carotid artery, cross-section, B-mode.

Figure 2. Internal carotid artery, external carotid artery, internal jugular vein, cross-section B-mode (left), colour-coded Doppler mode (right).

Figure 3. Carotid bifurcation, longitudinal section, B-mode.

Figure 4. Measurement of intima-media thickness in far wall of mid-common carotid artery.

Figure 5. Right carotid bifurcation, longitudinal section, power/intensity mode.

Figure 6. Left carotid bifurcation, longitudinal section, colour-coded Doppler mode.

Figure 7. Mid-internal carotid artery, longitudinal section, triplex mode.

Figure 8. Vertebral artery, longitudinal section, colour-coded Doppler mode.

The B-mode only is then turned on and the probe held vertically over the mid-sternomastoid to identify the VA in its intervertebral segment as a linear structure between the transverse processes of the cervical spines (Figure 8).

The intensity/power, then color-coded Doppler modes are used to study the entire VA including its proximal portions and its origin from the ScA. The Doppler mode is used as for the carotid study, evaluating the mid- and proximal VA and VA origin, as well as areas of turbulence.

The head is then turned the other way and the above processes repeated to study the contralateral carotid and vertebral arterial systems.

Challenges to a successful study include a patient's short and thick neck, high carotid bifurcation, breathlessness, and repeated swallowing.

PERFORMING A TRANSCRANIAL TRIPLEX EXAMINATION

The patient is placed supine, and the gel-covered probe in B-mode is placed gently over the temporal region above the ear in the transverse plane. The probe may be moved back and forth in the temporal window looking for the butterfly-shaped hypoechoic midbrain. Once found, the colour-coded Doppler is turned on and the vessels of the circle of Willis identified (Figure 9). The PCA wraps around the cerebral peduncle. More anteriorly, the MCA travels towards the probe while the ACA travels away.

Often, the contralateral ACA and PCA, and even MCA, may be seen. Areas of turbulence are interrogated by Doppler with the sample volume covering the whole artery to detect areas of significant stenosis, recording maximum velocities in the MCA, ACA and PCA; angle correction is not usually performed. The contralateral side is then examined in a similar manner.

The patient's head is then turned laterally, or the patient is sat up, with the head bent forward. The probe in B-mode in transverse plane is then placed over midline of the nape of the neck posteriorly, just below the occipital nuchae. The foramen magnum is identified as a hypoechoic round structure. The colour-coded Doppler is turned on and the VAs are identified entering the foramen magnum (Figure 10).

At times, the probe has to be placed a little to the side to obtain good images. The VAs are tracked further intracranially where they merge to form the BA which travels further cephalically. The posterior inferior cerebellar artery (PICA) is often identified as a large branch of the intracranial VA. Doppler is used to detect areas of significant stenosis in the VAs and BA.

With the power reduced to 10%, the lightly-gelled probe in transverse plane is gently placed over the eye ball and pointed slightly medially (= orbital window). The colour-coded Doppler is used to detect the OA which flows towards the probe, and Doppler used to determine velocities.

At greater depths, the CS is detected with flow towards then away from the probe. OA and CS velocities are recorded. The contralateral side is then examined in a similar manner.

The challenges include the absence of a temporal window on one or both sides in up to 30% of patients, especially those who are elderly, female or of Asian ethnicity. A restless patient may not allow a detailed examination to be performed.

Figure 9. Circle of Willis, left temporal window, colour-coded Doppler mode.

Figure 10. Vertebrobasilar junction, foraminal window, colour-coded Doppler mode.

PERFORMING A TRANSCRANIAL DOPPLER (TCD) EXAMINATION

The patient is positioned as for Transcranial Triplex examination. The gel-tipped small hand-held Doppler probe is placed over the temporal window and pointed inwards and a little anteriorly. The probe is manipulated at various angles to pick up the arterial signal of the MCA. The signal is traced laterally by varying the depth of the sample volume, then again medially till the ICA bifurcation is reached, recognised by MCA flows towards and ACA flows away from the probe. Tilting the probe inferiorly insonates the terminal ICA. The probe is then turned posteriorly and PCA examined. The contralateral arteries are examined in a similar manner.

The probe is then placed over the nape of the neck and the VAs and BA studied by tracking the VA signal through the foraminal window (Figure 11). Finally, with the power reduced to 10%, the probe is placed over the orbital window to investigate OA and CS. Both sides are examined.

Table 3. Identifying intracranial arteries by transcranial Doppler

Window	Artery	Orientation of probe	Depth of insonation (mm)	Direction of flow	Mean velocities (cm/s)
Temporal	MCA	Slightly anteriorly	40 – 65	Towards probe	60
	ACA	Even more anteriorly	65-80	Away	50
	tICA	Inferiorly	60-70	Towards	40
	PCA	Posteriorly	55-80	Towards (P1) Away (P2)	40
Orbital	OA	Slightly medially	40-55	Towards	20 (high resistance)
Window	Artery	Orientation of probe	Depth of insonation (mm)	Direction of flow	Mean velocities (cm/s)
	CS	Slightly medially	60-80	Towards or away	45
Foraminal	VA	If in midline, laterally If lateral, medially	40-90	Away	40
	BA	Midline towards nasion	80-100	Away	45
Submandibular	ICA	Towards ipsilateral eye	40-70	Away	40

The probe may also be placed below the mandible and the distal extracranial ICA insonated on each side in turn.

As TCD is a blind technique, vessels are identified by the window through which they are detected, orientation of probe, depth of insonation, and direction of flow (Table 3). Other challenges are as for transcranial triplex examination, including the absence of a temporal window on one or both sides, and the restless patient.

CLINICAL APPLICATIONS

Ultrasonography has a wide range of clinical applications in the management of ischaemic stroke

Intimamedial Thickness

Increasing intimamedial thickness (IMT) is associated with a moderately increased risk for cerebro- and cardiovascular events [5-10]. Statins statistically reduce the rate of intima-media thickness progression among middle-aged adults with raised LDL-cholesterol and moderate carotid IMT thickening; however, the clinical significance of this reduction is uncertain [11].

In general, IMT exceeding 1mm is considered thickened. IMT is usually measured along the far wall of the distal CCA just before the bifurcation using high-resolution B-mode imaging in the longitudinal section. The first marker is more superficial and is placed at the junction of the (dark) lumen and the (bright) intima. The second marker is placed more deep past the (bright) intima and (dark, presumed) media at the junction of the (dark, presumed) media and (bright) adventitia. Automated systems are available that will provide automatic estimations of IMT.

Extracranial Arterial Stenosis/Occlusion

Extracranial atherosclerosis typically occurs at the carotid bifurcation, possibly due to shear forces due to splitting of blood flows. Internal carotid plaque causes 10-20% of ischaemic strokes [12]. Plaques lead to cerebral ischemia by distal embolisation (of overlying thrombus, platelet clumps, lipid material), or haemodynamic effect of severe stenosis/occlusion leading to distal field ischaemia. Increasing carotid stenosis is associated with increasing risk of ipsilateral stroke and recurrent ichaemia (up to 26% at 2 years), which is reduced by early carotid endarterectomy [13].

Ultrasound is widely used as a screening tool for significant stenosis, and has even been employed as the primary screening tool for clinical trials [14]. Description of the plaque includes mention of the number of plaques, location, size, surface (smooth/ulcerated, the latter carrying higher risk of atheroembolism)), texture (homogenous/heterogenous), echogenicity (hypo-, iso-, hyper-echoic, with respect to the sternomastoid muscle, hypoechogenicity being of higher risk of plaque rupture), calcification (usually casting an acoustic shadow), and intraplaque haemorrhage (seen as a hypoechoic area within a plaque) (Figure 11).

There are a number of criteria that have been used to determine the degree of stenosis [15-17] (Figure 12).

Each neurovascular laboratory is encouraged to develop its own validated criteria for grading stenosis [18].

Figure 11. Left carotid bifurcation, longitudinal section, B-mode, showing plaques.

Figure 12. Proximal internal carotid artery, triplex mode, showing severe stenosis.

Figure 13. Right vertebral artery, foraminal window, transcranial Doppler, with high velocity showing stenosis.

Atherosclerotic stenosis may also occur at the origin of the VA, and less commonly along the mid-VA (Figure 13). The optimal management of VA stenosis (eg by stenting) is uncertain [19]. Diagnostic criteria for VA stenosis have been proposed [20].

Non-Atherosclerotic Disease - Carotid Dissection, Takayasu Disease, Radiation-Induced Atherosclerosis

Spontaneous carotid dissection causes 2% of all ischemic stroke, 25% among those below 45 years of age. It is due to a tear between the intima and medial layers of the artery, creating a false lumen and intramural thrombosis. Dissection typically starts just beyond the carotid bulb, and may extend intracranially, or at least till the ICA enters the petrous temporal bone [21]. While there is still controversy as to its management by anti-platelets or anticoagulation, making a diagnosis of the cause of a patient's stroke is invaluable; recurrence is uncommon [22]. Ultrasound findings include the detection of an intimal flap (rare), or a double lumen along the ICA beyond the bulb through which blood is able to flow. Most commonly, the ICA is totally occluded just beyond the bulb.

Takayasu arteritis is an inflammatory panarteritis, more frequent in Japan, South Asia, India and Mexico, that causes cerebral ischemia by the haemodynamic effects of progressive stenosis and occlusion of the arteries. The process starts in the aorta and ascends the carotid tree. Treatment includes the use of steroids in the active stage of the disease, and bypass and reimplantation surgery in burnt-out disease. On ultrasound, the inner layers of the arterial walls is diffusely thickened, starting at the proximal CCA, and extending cephalically [23].

The risk of stroke and transient ischaemic attacks is doubled by radiotherapy to the head and neck for malignancies. Radiation-induced atherosclerosis, the thickening of the arterial wall, is probably due to accelerated atherosclerosis due to radiation to the intima-medial layer as well as injury to the vasovasorum of the adventitia [24]. Endarterectomy is difficult to

perform in the scarred tissues; stenting has a high re-stenosis rate [25]. On ultrasound, the atherosclerosis is restricted to the parts of the artery that lay within the field of radiation, with a sharp cut-off in the area of abnormality between the irradiated and non-irradiated parts of the artery.

Subclavian Steal

While usually asymptomatic, the patient may complain of dizziness with excessive use of an upper limb. The pulse and blood pressure may be weaker in that limb. The underlying process is severe stenosis/occlusion of the ScA proximal to the origin of the VA. Severe symptomatic stenosis may be treated by surgery or stenting [26].

On ultrasound, the earliest indication is a transient sharp deceleration of blood flow after the first systolic peak, producing a notch and giving rise to two systolic peaks: the first is sharp, the second is blunt. As the subclavian steal worsens, the systolic notch becomes more obvious and the second systolic peak decreases. The nadir of the notch becomes lower and lower until it reaches and finally crosses the baseline. Flow reversal during systole is initially minimal, but increases until there is complete reversal of flow throughout the cardiac cycle. The steal can be accentuated by the cuff test where a blood pressure cuff is placed over the upper arm, inflated just beyond systolic blood pressure and maintained for a few minutes, and then suddenly completely released (Figure 14).

Figure 14. Subclavian steal - alternating flow in vertebral artery accentuated with cuff manoeuvre.

Intracranial Arterial Stenosis/Occlusion

Intracranial atherosclerosis accounts for about 8% of ischaemic stroke in North America and 50% in Asia. The risk of recurrent stroke is 15% per year [27]. Intracranial atherosclerosis typically occurs at sites of arterial bifurcation or merging, or areas of turbulent flow. These sites include the CS, tICA, M1, A1, P1, vertebro-basilar junction, mid-BA, and top of the BA. Optimal management is still uncertain – anti-platelets may be sufficient [28, 29].

Various ultrasound diagnostic criteria have been proposed [30]. Just as for carotid disease, each neurovascular laboratory is encouraged to develop its own validated criteria for grading stenosis.

Collateral Flow As a Result of Severe Stenosis/ Occlusion

Collateral blood flow via extracranial and intracranial anastomoses provides much needed blood supply and reduces the risk of haemodynamic stroke.

In ICA severe stenosis/occlusion between the carotid bifurcation and the origin of OA, extracranial anastomosis between the ECA and ICA via the OA results in increased ipsilateral ECA flow with reversal of the OA flow direction to enter the distal ICA.

Ipsilateral A1 flow is reversed as flow increases in the contralateral A1 and crosses the AComMA to enter the A1; ipsilateral P1 flow may also increase and across the PComMA to enter the distal ICA.

In CCA occlusion, flow may reverse along the ipsilateral ECA to feed the ipsilateral ICA. In VA occlusion, increased flow may occur in the contralateral VA to feed the BA.

Right-To-Left Shunting

Approximately 40% of ischaemic strokes among the young are cryptogenic; more than half have a patent foramen ovale that may provide a conduit for a thrombus from the right-sided circulation to cross into the left-sided circulation and enter the cerebral circulation [31]. Optimal therapy is controversial – closure, anti-coagulants, anti-platelets are used [32].

While the ‘gold standard’ for the diagnosis of PFO is transoesophageal echocardiography (TEE), TCD of the MCA has been shown to have a very high sensitivity and specificity [33]. For those patients with poor temporal windows, the foraminal window with the insonation of the BA can be used [34].

There is a consensus recommendation for the performance of a ‘bubble-TCD’ for the detection of a right-to-left shunt (RLS). This involves the rapid injection via a large bore needle placed in the antecubital region of a well-agitated mixture of 9 ml of saline and 1 ml of air, while insonating the MCA.

The presence of an RLS is indicated by the swift occurrence of high intensity transient signals (HITS) presumed to be microbubbles (MB) - 0 MB (negative result); 1-10 MB; >10 MB with no curtain, and curtain [35]. The optimal position may be with the patient sitting and test performed with the Valsalva manoeuvre [36]. Approximately 10% of RLS are extra-cardiac eg pulmonary vascular malformations.

Embolisation

The presence of HITS gives a 7 to 13-fold increase in the risk of recurrent stroke [37, 38]. HITS are attributed to microemboli from a more proximal source – thrombi (eg from atrial fibrillation, prosthetic cardiac valves, atherosclerotic plaques extra or intracranially), gas

bubbles (eg from prosthetic cardiac valves). They are reduced by double-antiplatelet therapy, but reduction in clinical events has not been shown [39, 40].

The TCD probe is fixed on a head frame and the artery closely monitored, preferably for at least 30 mins, on at least 3 occasions. There are consensus criteria for Doppler diagnosis – transient signal usually lasting less than 300 milliseconds, amplitude usually at least 3 dB higher than that of the background flow signal, signal is unidirectional within the Doppler spectrum, and signal is accompanied by an audible “snap,” “chirp,” or “moan” [41].

Intra-Operative Monitoring during Carotid Endarterectomy (CEA), Coronary Artery Bypass Grafting (CABG)

Intracranial HITS are frequently seen during CEA, especially during the mobilization of the carotid artery and during cross-clamping, and even more-so after release of the cross clamps after arterial wall closure. These are presumed to be due to emboli from the atherosclerotic plaques, or even air that entered the surgical site during surgery.

Similarly, HITS are seen during CABG. These may be due to gaseous bubbles from the heart-lung machine or atherosclerotic material during reversed flow along the aorta.

During CEA, due insufficient intracranial collaterals, MCA flow may fall precipitously during ipsilateral cross-clamping – some surgeons would insert a shunt across the surgical incision site in this setting. Monitoring is achieved by using a head frame holding the monitoring probes.

Post-Surgery/Stent Assessment

Patency of the carotid arteries immediately after CEA or stenting, intra/post-operative carotid dissection, in-situ thrombosis, are detected by ultrasound, which may require re-surgery/stent. The occurrence of subsequent re-stenosis some time after surgery/stenting is also easily assessed. If a patient develops post-procedure ipsilateral cortical signs, the finding of extremely high ipsilateral intracranial velocities may support the diagnosis of hyper-perfusion syndrome, necessitating blood pressure reduction.

Cerebrovascular Reserve to Predict Stroke Risk

Vasodilation is one of the cerebrovascular responses to cerebral ischaemia so as to maintain blood flow when there is blood flow reduction. Carbon dioxide (CO₂) is a potent cerebral vasodilator. A reduced or failed vasodilatory response to CO₂ would indicate that vasodilation is maximal, no more vasodilation is possible ie there is absent/reduced cerebrovascular reserve (CVR). Reduced CVR is a marker for recurrent cerebral ischaemic events, and may be used to select patients for superficial temporal artery-middle cerebral artery bypass and carotid surgery [42].

The breath holding index (BHI) is one method of assessing CVR. It is determined by measuring the mean velocity before and after breath-holding: $BHI = (\text{velocity at end of breath-holding} - \text{velocity at start of breath-holding}) \times 100 / (\text{velocity at start of breath-holding})$

x number of seconds of breath-holding). A BHI < 0.69 indicates an increased risk of ipsilateral ischaemic cerebrovascular events [43].

Sonothrombolysis

Ultrasound is able to assist in the lysis of blood clots by a number of mechanisms, including clot agitation to break up clots and thus increase the surface area for natural or administered thrombolytic molecules or agents to act. The administration of ultrasound during the administration of systemic thrombolytic agents has been shown to improve recanalisation, without harm or benefit on death or dependency at 3 months [44].

The ultrasound probe is fixed to the head by a frame with the ultrasound beam focused at the site of occlusion for an hour. Recanalisation is heralded by the return of flow velocities to a more normal level at which time the insonation can be terminated.

PHYSICIAN ACCREDITATION

The performance of a competent neurosonological examination will greatly assist in patient care. There are a number of international accreditation examinations available for physicians held a number of times in the year in various cities. They are offered by the World Federation of Neurology Neurosonology Research Group as well as the American Society of Neuroimaging [45, 46].

CONCLUSIONS

Ultrasound is a safe, useful and versatile technique in the management of patients with cerebrovascular disease, not just for diagnosis but potentially also for treatment (sonothrombolysis).

Further research and clinical trials will provide more information as to the role of neurosonology in the management of ischaemic stroke.

Chapter 54

MODELING AND OPTIMAL DESIGN OF POWER HIGH STROKE PIEZOELECTRIC ACTUATORS FOR ROTORCRAFT APPLICATIONS

S. Shevtsov*, M. Flek and I. Zhilyaev

Aircraft Engineering Laboratory at South Center
of Russian Academy of Science, Rostov-on-Don, Russia
Rostvertol Helicopters, Rostov-on-Don, Russia[†]

ABSTRACT

Because of helicopter main rotor is a source of external noise, cabin noise and intensive vibrations, the problem of active vibration preventing and suppression attracts attention of many engineers and scientific investigators last three decades. The mentioned vibrations are caused by the non-symmetrical and unsteady rotor aerodynamics. Last years to realize the advanced helicopter rotor control the Active Trailing Edge (ATE) or Active Flap (AFC) concepts have been proposed. According to AFC concept the small flap which is placed on the distance close to 0.7 of the blade radius, can deflect upwards or downwards, and due to this the blade changes the aerodynamic properties, and vibration level can be decreased.

Very effective and structurally simple solution for driving whole blade or active flap, is the use of power piezoelectric devices. Such piezoelectric actuator drives an active flap hosted on the helicopter rotor blade to change its aerodynamic properties at rotor rotation. As the flap deflection properly synchronized with the azimuthal angle of rotor blade, such active flap control devices allow us to significantly reduce the noise and vibration level of helicopter.

Despite the inherent ability to create of very high forces, all piezoelectric actuators have some drawbacks, among which an incapability to produce enough large displacement, and bad withstanding an external tensile stress. These limitation is forced to develop the different structures for the stroke amplification. This article concern a structural optimization problem for a flexensional piezoelectric actuator which consists

of the high power piezoelectric stack and polymeric composite shell intended for amplification of the stroke. To formulate an optimization problem we parametrize the shape of the amplifier's shell by the rational Bezier curves, which parameters (coordinates and weights of the control points) are changed iteratively by genetic algorithm according to the fitness function value calculated by the finite element model of the transducer with varied geometry. We used the fitness function as the shell's deflection under action of external force. Finally, we demonstrate some optimization results, which confirmed the proposed approach.

1. INTRODUCTION

Reducing high frequency dynamic structural loads that increase the wear of components by minimizing the corresponding disturbances, is an important aim for aerospace designers [1-3]. Besides, the modern aircraft must meet the strong requirements to limits for emitted noise. The helicopter vibrations are mainly excited by periodic forces generated by the main rotor and transferred through the rotor hub and the gearbox into the fuselage. Most intensive vibrations are generated at forward flight and because of the blade-vortex interaction (BVI). At the forward flight with the airspeed V the chordwise velocity U of a blade element is given by

$$U = \Omega r + V \sin \psi, \quad (1)$$

where ψ is the blade azimuthal position, Ω is the rotor angular velocity, and r is the blade element distance from the rotor axis. On the retreating side the component of rotational velocity and horizontal velocity are subtractive and a region of reversed flow will exist. Since the flow in the reversed flow region is from trailing edge to leading edge, it has the effect of pushing the rotor around the mast thereby extracting power from the airflow. BVI is an example of an intense vertical velocity field with high velocity gradients. While passing an airfoil at a predetermined distance, a convecting vortex of positive circulation produces a downwash velocity while upstream of the blade (airfoil), and this changes to an upwash as it moves downstream. This situation leads to a rapidly and continuously changing angle of attack, resulting in highly unsteady aerodynamic loads [4].

Different approaches have been explored to achieve a reduction of the helicopter vibration. Passive means, either located in the rotating or fixed system, aim at exclude the transfer of the exciting forces into the fuselage by especially tuned absorbers. Research activities of last 40 years showed the high potential of active rotor control with a higher harmonic blade pitch variation for vibration reduction [4]. In this case a blade pitch oscillation with harmonics of the rotor rotational frequency is superimposed to the collective and cyclic blade pitch (see Figure 1, a). The Higher Harmonics Control (HHC) provides that the control signal was fed into actuators located beneath the swashplate. The promising theoretical and experimental results led to the development of the Individual Blade Control (IBC) system (see Figure 1, b), where the original pitch links located above the swashplate are replaced by power actuators which change the incidence (or pitch) angle of the blades. Both technologies work with a higher harmonic excitation of the blade pitch at the blade root, which is a very energy-consuming, and also can lead to the blades excitation on first twisting

vibration mode [3]. With an active trailing edge (ATE) flap the excitation is not introduced at the blade root, but localized at a distance 75 – 90% of the blade radius (see Figure 2). ATE concept can be implemented in the form of flexible or turned trailing edge flap, and as the locally morphing airfoil [8].

Figure 1. HHC vs IBC concepts [3].

Figure 2. SMART rotor blade with piezoelectric actuator driving the trailing edge flap [6].

The Actively Controlled Flaps are generally 15% of a chord length and most known structures are driven by the power piezoelectric transducers. Due to the high operating forces and frequency, smart materials such as piezoelectric actuators are well adapted for this task, but relatively large displacements require some sort of mechanical amplification of these devices movement. Because of the very small displacements created by the piezoelectric devices some design solutions to amplify the stroke of PZT actuators are proposed [7, 9].

The most important requirements to the piezoelectric actuator for the active flap design are the following [2]:

- i. big force and large displacement in compact sizes,
- ii. high resolution within the micrometer range,
- iii. very short response time less than 1 ms,
- iv. life time greater than 10¹⁰ cycles,
- v. low voltage supply less than 150V DC, no backlash and no play,
- vi. low power consumption when statics,
- vii. severe environment compatibility (broad temperature and moisture ranges).

Among the known structural concepts of actuators most adoptable properties had the flextensional actuator which consist of the high power piezoelectric stack and shell which supply the stroke amplification (see Figure 3).

Figure 3. Piezoelectric amplified stack with steel (a) and polymeric composite (b) shell [2].

These actuators provide a high stiffness and relatively large displacements. On the other hand, their mass is not optimized and the metallic shell implies a large penalty on the mass. In order to improve the mass of these flextensional actuators a carbon composite is used instead of metal for the frame. Figure 4 demonstrates the mounting of actuators on the rotor blade and shows the transmission of aerodynamic forces to the actuator through the levers. These forces deflect the flap in opposite direction to its active deflection. Because of acting aerodynamic forces a higher flap deflections require larger and therefore heavier actuators, but additional mass is needed to equilibrate the center of mass of the blade close to active flap mounting.

Figure 4. Mounting of active flap and driving piezoelectric actuators on the rotor blade [6].

In order to realize the active flap on the real-world five-bladed helicopter we need to optimize the mechanical properties of the considered flextensional actuator. Primarily we investigate by the finite element method (FEM) the properties of actuator with most widely used elliptic composite shell. Next we describe the shape of the shell by the rational Bezier curves, which allow the good flexibility and to simultaneously optimize the stiffness and operating stroke. An optimization problem will be stated with the given performance of piezoelectric material and the constraints will be imposed on the acting external force as well as the coordinates of the points controlling the Bezier curve behavior. As the fitness function we accept the actuator's stroke at permissible operating voltage on the PZT stack and given external force. Because of total number of degrees of freedom for this problem is very big, we use genetic algorithm implemented in the soft package MATLAB (Genetic Algorithm Toolbox) and simplified one-quarter 2D FEM model of actuator worked in Comsol Multiphysics. Finally we demonstrate the effectiveness of the developed optimization method and significantly improved properties of the optimized actuator.

2. FINITE ELEMENT MODELING OF FLEXTENSIONAL ACTUATOR WITH ELLIPTIC SHELL

We have investigated only actuators with shell made of glass fiber epoxy polymeric composite which had the longitudinal Young modulus $3 \cdot 10^{10}$ Pa and density 1850 kg/m^3 . Technology of the shell manufacturing includes the winding of unidirectional glass-fiber tape on a mandrel with appropriate shape, then curing in autoclave until the complete solidification. The size of the finished shell should provide a prestress for the assembled piezoelectric stack for a double-side acting actuator. Stack was constructed of a multilayer piezoelectric ceramic PZT-5H, the thickness of each layer, polarized in thickness, was 0.5 mm. Driving electric potential was taken as 400 V. Geometry of a typical FEM model is presented in Figure 5.

Figure 5. Geometry of actuator’s FEM model with elliptic shell and varying ratio of the ellipse semiaxes.

Figure 6. Dependencies of the actuator's stroke (a), amplification ratio (b), and reaction force applied to the PZT stack (c), and compressive deformation of the stack under this reaction force (d) on the external force for the different dimensional parameters of composite shell.

In our numerical experiments we used shell geometry with the thickness 8 mm and 12 mm; major semi-axis was always 100 mm, whereas the small semi-axis took values 40, 50, 60, 70 mm.

The FEM static analysis was performed as follows. After applying of the driving potential the stack lengthened, deforming the shell and causing it to contraction in the vertical direction. Then to the executive surfaces of the shell (small quadrilateral planes) the gradually increasing tensile force was applied. When the structure was loading the values of operating stroke, applied reaction force and deformation of piezoelectric stack were monitored. As soon as the executive surfaces displacement returns to zero, the blocking force is recorded.

Then to the executive surfaces of the shell (small quadrilateral planes) the gradually increasing tensile force was applied. When loading, the values of operating stroke, applied reaction force and deformation of piezoelectric stack were measured. Some simulation results

are presented in Figure 6, where, for example, the acronym 40-100-8 means as follows: semi-major axis of 100 mm, small axis of 40 mm, thickness 8 mm.

One can see from the plots (Figure 6, a, d) that the total compliance of actuator is determined by the shell, not PZT stack that has a greater stiffness. Indeed, total displacement of actuator (40-100-8) at the loading force 2 kN consists of 0.23 mm, whereas deformation of PZT stack is equal to 0.01 mm, only. This can be explained by the results of FEM modeling. Figure 7 shows von Mises stress distribution in shell before and after applying the external tensile force. As one can see the stress-strain state along the shell is non-homogeneous, thus we can enhance the actuator performance by varying the shell thickness distribution.

As might be expected, thicker shell has more stiffness, but lesser free stroke. Dependence of the actuator's parameters on the ratio of the elliptic shell axes is also essential. The more shallow shells provide greater amplification, but lesser ability to counteract external loads. This fact is illustrated in Figure 8, where dependencies of the amplification ratio and blocking force for the different shell dimensions are presented.

These preliminary results justify the need and opportunity to optimize the shell's geometry. This optimization can be performed by varying the shape of the generatrix and thickness distribution of the shell.

Figure 7. Deformed shape and von Mises stress distribution in polymeric composite shell before (above) and after (below) applying the tensile force to the upper and lower plate of shell (Results of static FEM simulation. Von Mises stress is illustrated by the colour: most intensive red colour corresponds to the value 35 MPa. All deflections are increased in 50 time).

Figure 9. Representation of the shell's profile by the 3rd order rational Bezier curves.

3. GA BASED OPTIMIZATION OF THE SHELL GEOMETRY

As the objective function is advisable to choose the operating stroke h_{op} at the given external load F_{act} (in our case this value is 600 N). To describe the shape of the generatrix with the necessary flexibility we use the rational Bezier curves because of these lines are inherent for the used FEM software Comsol Multiphysics. According to the adopted assumptions the one-quarter of the symmetrical shell can be presented as two branches, each of which consists of three 3rd order Bezier curves (see Figure 9). The rational Bezier curve of n -th order, defined by the $(n+1)$ control points P^i , is described by the equation:

$$R(u) = \sum_{i=0}^n w_i B_n^i(u) P^i \Big/ \sum_{i=0}^n w_i B_n^i(u), \quad (2)$$

where $B_n^i(u)$ are the Bernstein polynomials, defined as

$$B_n^i(u) = \frac{n!}{i!(n-i)!} u^i (1-u)^{n-i}, \quad (3)$$

w_i , $i = 0, 1, \dots, n$ are the weights of the control points, and u is the parameter runs through the values from 0 to 1.

At optimization process, external dimensions of the shell remain to be unchanged, so, only shape of the generatrices is optimized. In order to supply C^1 continuity at the connection points (denoted by “×”) it is necessary to impose additional constraints on the location of the control points, which are adjacent to the point connection of two curves. If P^c is the vector coordinates of connection point, P^{lc} is the vector coordinates of a point adjacent to the left-to-point connection, then vector coordinates of a point adjacent to the right-to-point connection is

$$P^{cr} = 2P^c - P^{lc} \quad (4)$$

Figure 9 shows the equality of the corresponding edges of the control polygon. The placement on the vertical (horizontal) lines of points adjacent to the terminal points (denoted as “+”) of the generatrices allows us to automatically satisfy condition of C^1 continuity due to symmetry of the shell (see Figure 9). So, we have 21 degrees of freedom for the points coordinates, and 18 degrees of freedom for the weights, at last, total number of DoFs is 39.

All control points positions are constrained by the system of inequalities:

$$\begin{cases} X_i > X_{(i-1)}, & i \in [1; (n-1)]; \\ Y_i < Y_{(i-1)}, & i \in [2; n], \end{cases} \quad (5)$$

by the equalities for connection points from the relationship (4)

$$\begin{cases} X_0 = 0; & Y_0 = b^{in,out}; \\ Y_1 = b^{in,out}; \\ X_n = a^{in,out}; & Y_0 = 0; \\ X_{n-1} = b^{in,out}, \end{cases} \quad (6)$$

where the dimensions of the external generatrix a^{out}, b^{out} are fixed, but the dimensions of the internal generatrix are satisfied by the relationships:

$$\begin{cases} a^{out} > a^{in} = \text{fixed} \\ b^{out} > b^{in} = \text{varied} \end{cases} \quad (7)$$

Figure 10. Geometry and displacements field for optimized FEM model of the flextensional actuator.

All weights also are constrained by the system of inequalities. Each of the three Bezier curves, which form the generatrix, is described by its own equation (2). But to ensure the smoothness of generatrix, end points of one curve and the initial point of the connecting curve have the same weight. So, we have the following system of constraints for weights:

$$\begin{cases} w_0 = 1; \\ 0 < w_i < 5, \quad i \in [1; n]. \end{cases} \quad (8)$$

After a number of numerical simulations some additional restrictions are introduced to narrow the range of the coordinates of control points

$$\sum_{k=1}^i \xi(k, a^{in,out}) - 0.25 \xi(i, a^{in,out}) < X_i < \sum_{k=1}^i \xi(k, a^{in,out}) + 0.25 \xi(i, a^{in,out}), \quad (9)$$

where $\xi(i, a^{in,out}) = \frac{a}{372} [64 - (i-1)^2]$ $i = 1, \dots, n-1$.

These constraints allow us to agree the density of the control points with the curvature of the generatrix, and thereby significantly reduce the search area. This is very important for a problem with large number of DoFs. Similar optimization problems can be successfully solved only by the genetic algorithm. Therefore we have used the Genetic Algorithm Toolbox MATLAB which has the advanced optimization means and direct access to the FEM computation.

To reduce the computational cost, our FEM model was very simplified. Due to symmetry of the shell we consider one-quarter of actuator's structure (see Figure 10). All material

properties and displacements are considered as linear. Quadrilateral FEM mesh consists of near 500 elements. FEM model works in the Structural Mechanics – Piezoelectric mode. At each iteration step, GA Toolbox rebuilds the shell geometry, remeshes it, and performs the parametric static analysis. The calculated value of the actuator stroke is passed to the GA Toolbox, which changes the value of the design variables according to the constraints. Whole computation flowchart is controlled by MATLAB which in turn refers to modules that perform the parametric finite element analysis. These modules are implemented as standard MATLAB's m-files. Most important GA settings are: population size is 50, elite count is 5, crossover is configured as scattered, mutation – as adaptive feasible, used hybrid function is “fmincon”.

Figure 11. Compared actuators with different forms of shells.

Figure 12. Performance parameters of three compared flextensional actuators with different shells.

4. RESULTS AND DISCUSSION

The developed optimization technique has been successfully applied to the different flextensional actuators with polymeric composite shell of the same outer dimensions $180 \times 70 \times 24 \text{ mm}^3$. Multilayered PZT stacks with dimensions $144 \times 24 \times 16 \text{ mm}^3$ were controlled by the same voltage (electric field 400 V/mm). All optimized actuators with improved parameters have a more complicated shape of the generatrix and a varied thickness along it. For the case when the shape of external generatrix is restricted by the smooth curves with no kinks (structural restrictions due to complexity of mould for the shell cure) all outer control point were fixed in positions appropriate to the Cassini oval [12] which is described by the equation:

$$r^4 - 2a^2r^2 \cos 2\theta = b^4 - a^4, \quad (10)$$

where the parameters a, b , which determine the shape of curve, are linked by the relationship $b/a > 1$, and spatial coordinates vary with the polar angle θ as $x = r \cos \theta$; $y = r \sin \theta$.

Three actuators with different shells have been compared: with elliptic, two-sided Bezier, and Cassini – Bezier generatrices (see Figure 11).

Figure 13. Diagram of the best fitness convergence.

The following plots (see Figure 12) shows comparative data of three investigated similar size actuators: with the elliptic shell and with shells optimized by the proposed method. These data demonstrates several best features of the optimized actuators. Actuator with two generatrices in the form of optimal Bezier curves is the best. At the load 40 kgf it provides a stroke half times greater than the actuator with a simple elliptical shell. In addition, at the same external load, it transmits a much smaller force on the piezoelectric stack that allows us to reduce its cross-section and hence the total mass of actuator. These advantages are crucial, since the power actuators are designed to move against the acting forces and should not change the mass balance of rotor blade.

Actuator with Cassini – Bezier shell has the intermediate parameters, but more preferable compared to simple elliptic shell.

The total computer time engaged by the process of optimization (about 500 epochs) was 5 – 6 hours on i5 computer. To illustrate character of optimization process the typical diagram of the fitness function convergence is presented in Figure 13. Here the solid red line shows the value of stroke for the actuator with elliptic shape. For all investigated structures the optimization using genetic algorithm and chosen fitness function ensures good repeatability and finite element mesh independence.

The developed method has been used to design the actuators for helicopter rotor control.

CONCLUSION

To provide an actively controlled flap for a helicopter rotor blade an optimization method for flextensional piezoelectric actuator has been developed and tested. This method is based on the representation of the shape of polymeric composite shell by the rational Bezier curves, whose parameters (coordinates and weights of the control points) are the design variables for the optimization algorithm. The optimization process is controlled by the genetic algorithm Toolbox MATLAB, which access a finite element model of device, calculates the objective functional (the stroke of actuator against given external load), and modifies design variables to achieve the optimum. The effectiveness of the proposed method is examined by comparative analysis of the prototype structure with elliptic shape of the composite shell. Our results prove the usefulness of the developed optimization methodology and its attractiveness not only for the aircraft applications but also in many areas of electromechanics, automatics and nanopositioning.

Chapter 55

COMBINATION TREATMENT OF REPETITIVE TRANSCRANIAL MAGNETIC STIMULATION AND INTENSIVE OCCUPATIONAL THERAPY: A NOVEL THERAPEUTIC APPROACH FOR UPPER LIMB HEMIPARESIS AFTER STROKE

Wataru Kakuda and Masahiro Abo

Department of Rehabilitation Medicine, Jikei
University School of Medicine, Tokyo, Japan

ABSTRACT

Recently, low-frequency repetitive transcranial magnetic stimulation (rTMS) applied to the non-lesional hemisphere has been reported to improve motor function of the paretic upper limb after stroke. On the other hand, some clinical studies have confirmed the beneficial effect of intensive occupational therapy (OT) such as constraint-induced movement therapy for upper limb hemiparesis after stroke. Both low-frequency rTMS over the non-lesional hemisphere and intensive OT can facilitate neural activity of the lesional hemisphere, which compensates for impaired motor function of the paretic upper limb. We postulated that combined application of low-frequency rTMS and intensive OT might accelerate the improvement of motor function of the paretic upper limb in post-stroke patients. Therefore, we newly developed a 15-day in-patient protocol of combination treatment of these two interventions for this patient population. In the protocol, each patient was scheduled to receive 22 sessions of combination treatment with 20-min low-frequency rTMS of 1 Hz to the non-lesional motor cortex followed by intensive OT over 15 consecutive days. The program of intensive OT consisted of 60-min one-to-one training and 60-min self-exercise. The results of the multi-center study including more than 200 patients showed that our proposed protocol is a safe and feasible intervention. In addition, the protocol improved significantly motor function of the affected upper limb in studied patients. Furthermore, it seems that concomitant introduction of daily levodopa administration and botulinum toxin type A injection can augment the efficacy of the protocol. It may be a promising strategy to apply more potent

modalities of TMS such as theta burst stimulation instead of conventional low-frequency rTMS, combined with intensive OT. In conclusion, our proposed combination treatment of low-frequency rTMS and intensive OT can be a novel therapeutic intervention for post-stroke patients with upper limb hemiparesis.

INTRODUCTION

In this chapter, we first discuss the therapeutic concept of repetitive transcranial magnetic stimulation (rTMS) combined with intensive occupational therapy (OT) for post-stroke patients with upper limb hemiparesis. In the second part, we describe our experience using the combination treatment of low-frequency rTMS and intensive OT in the same patient population. We also comment on future directions regarding this therapeutic modality in research and clinical practice.

THERAPEUTIC CONCEPT OF rTMS COMBINED WITH INTENSIVE OT FOR UPPER LIMB HEMIPARESIS AFTER STROKE

Low-Frequency rTMS As a Therapeutic Tool

Transcranial magnetic stimulation (TMS) is a painless, safe procedure involving non-invasive brain stimulation (Hallett, 2007). Applying TMS in a repetitive manner, i.e., repetitive TMS (rTMS), can modulate local cortical neuronal excitability with effects ranging from up-regulation (facilitation) to down-regulation (suppression) of neuronal activity, depending on the frequency of stimulation (Huerta and Volpe, 2009). High-frequency rTMS (≥ 5 Hz) facilitates local neural activity, whereas low-frequency stimulation (≤ 1 Hz) depresses such activity (Chen et al., 1997; Maeda, Keenan, Tormos, Topka, and Pascual-Leone, 2000; Muellbacher, Ziemann, Boroojerdi, and Hallett, 2000; Wu, Sommer, Tergau, and Paulus, 2000). In cases of impaired neurological function due to stroke, rTMS as a therapeutic intervention should be applied to activate the cortical areas that compensate for the function. Using neuroimaging studies, some researchers revealed that the perilesional areas in the lesional hemisphere play an important role in motor functional recovery of the affected upper limb after stroke (Cramer et al., 1997; Feydy et al., 2002; Marshall et al., 2000; Weiller, Ramsay, Wise, Friston, and Frackowial, 1993). Based on these findings, we hypothesized that neural activation of the perilesional areas can induce motor functional recovery of the paretic upper limb after stroke. Considering the bidirectional effects of rTMS, two therapeutic approaches to activate the perilesional areas have been suggested; the direct and indirect approaches.

In the direct approach, facilitatory high-frequency rTMS is applied over the lesional hemisphere to directly up-regulate neural excitability in the perilesional areas (Figure 1). On the other hand, in the indirect approach, inhibitory low-frequency rTMS is applied to the non-lesional hemisphere to suppress neural activity of the non-lesional hemisphere with subsequent suppression of interhemispheric inhibition towards the lesional hemisphere. Finally, the perilesional areas are disinhibited from the interhemispheric inhibition, resulting in up-regulation of the neural activity in these areas (Figure 2).

Whether the direct or indirect approach is more beneficial for upper limb hemiparesis after stroke remains to be clarified. Rossi, Hallett, Rossini, and Pascual-Leone (2009) have suggested that high-frequency rTMS poses a clear risk of seizure induction. In addition, low-frequency rTMS produces less site discomfort during stimulation than high-frequency rTMS.

Therefore, the indirect approach using low-frequency rTMS is safer and likely to be more widely applicable as a therapeutic intervention for upper limb hemiparesis after stroke compared with the direct approach using high-frequency rTMS. As shown in Table 1, the efficacy of low-frequency rTMS over the non-lesional hemisphere was established in many studies, and all showed significant improvement in motor function of the affected upper limb in post-stroke patients (Dafotakis et al., 2008; Fregni et al., 2006; Kirton et al., 2008; Mansur et al., 2005; Nowak et al., 2008; Takeuchi et al., 2005; Takeuchi et al., 2008).

Figure 1. Direct approach. High-frequency rTMS is applied to the lesional hemisphere, to directly up-regulate neural excitability of the perilesional areas.

Figure 2. Indirect approach. Low-frequency rTMS is applied to the non-lesional hemisphere, resulting in the reduction of interhemispheric inhibition towards the lesional hemisphere. Subsequently, the perilesional areas are disinhibited from the interhemispheric inhibition and activated.

Notably, Fregni et al. (2006) indicated that improvement gained by daily application of low-frequency rTMS over a period of five consecutive days was maintained for up to 2 weeks after treatment cessation.

Based on these reports, we considered that low-frequency rTMS is a potentially useful therapeutic tool for upper limb hemiparesis after stroke.

Combined Application of Low-Frequency rTMS and Intensive OT

Based on the beneficial effect of low-frequency rTMS over the non-lesional hemisphere on motor function of the paretic upper limb after stroke, combining this rTMS modality with another therapeutic intervention with proven beneficial effects for upper limb hemiparesis could enhance the treatment outcome. As the results of a meta-analysis, Langhorne, Coupar, and Pollock (2009) indicated that constraint-induced movement therapy (CIMT), a typical form of intensive OT, is the most effective rehabilitative intervention available. In addition, the results of the Extremity Constraint Induced Therapy Evaluation (EXCITE) trial of more than 200 post-stroke patients confirmed the significant benefit of CIMT for treating upper limb hemiparesis after stroke (Wolf et al., 2006). As an underlying mechanism of beneficial effects with intensive OT, it has been reported that intensive OT can facilitate neural activity of perilesional areas in the lesional hemisphere (Lewy, Nichols, Schmalbrock, Keller, and Chakeres, 2001; Wittenberg et al., 2003). We thus speculated that the combination treatment of low-frequency rTMS and intensive OT could produce greater improvement in motor function of the affected upper limb, through further facilitation of neural activity in the lesional hemisphere, compared with rTMS alone. Figure 3 illustrates our therapeutic concept using such therapeutic interventions.

As a pre-conditioning intervention, low-frequency rTMS is applied first to maximize brain plasticity in the lesional hemisphere. Following rTMS application, intensive OT was then provided to further facilitate neural activity in the perilesional areas, with consequent beneficial functional reorganization in the lesional hemisphere. In other words, we assumed that low-frequency rTMS over the non-lesional hemisphere conditions the compensating areas in the lesional hemisphere to be more responsive to the effects of intensive OT.

Figure 3. Therapeutic concept of our proposed combination treatment. Prior to intensive OT, low-frequency rTMS is applied as a pre-conditioning intervention for maximizing brain plasticity.

In-Patient Protocol of Combination Treatment

In 2008, we introduced the combination treatment of low-frequency rTMS and intensive OT as a 15-day protocol for post-stroke in-patients with upper limb hemiparesis at our university hospital (Kakuda et al., 2010). After confirming the protocol safety in a small number of patients at our university hospital, some other hospitals in Japan also started to provide the same protocol of combination treatment. Currently, eight hospitals in different parts of Japan (Jikei University Hospital, Jikei Daisan Hospital, Shimizu Hospital, Tokyo General Hospital, Nishi-Hiroshima Rehabilitation Hospital, Aizawa Hospital, Suwanomori Hospital, and Kimura Hospital) use our proposed protocol of the combination treatment as an in-patient intervention. All these hospitals have an at least 30-bed ward/section specially equipped for long-term rehabilitation of stroke patients, two or more board-certificated physicians, and at least five occupational therapists with expertise in stroke rehabilitation. Prior to the introduction of the protocol, physicians and therapists at each institution received training at our university hospital. All participating hospitals use the same inclusion criteria, therapeutic protocol, and clinical measures for assessment of the protocol efficacy.

Inclusion Criteria

The following are the currently used criteria in the above hospitals to determine the suitability of post-stroke patients for the treatment: 1) Brunnstrom stage for hand-fingers of 3-5 (ability, at least subjectively, to flex all the fingers of the affected upper limb in full range of motion); 2) age at intervention of 18-90 years; 3) more than 12 months between the onset of

stroke and treatment; 4) history of a single stroke only (no bilateral cerebrovascular lesion); 5) no cognitive impairment with a pretreatment Mini Mental State Examination score of more than 26; 6) clinical confirmation of the plateau state, representing no increase in the Fugl-Meyer Assessment (FMA) score assessed by an occupational therapist from the institution in the latest 3 months; 7) no active physical or mental illness requiring medical management; 8) no recent history of seizure (within one year preceding the intervention); 9) no documented epileptic discharge on pretreatment electroencephalogram; 10) no current use of antiepileptic medications for the prevention of seizure; and, 11) no pathological conditions known to be contraindications for rTMS, as listed in the guidelines of Wassermann (e.g., intracranial implants, cardiac pacemakers, pregnancy) (Wassermann, 1998).

Time Schedule of 15-Day Protocol

All patients were hospitalized in order to receive the 15-day protocol. During hospitalization, each subject received 22 treatment sessions, each comprising 20 minutes for application of low-frequency rTMS and 120 minutes of intensive OT (two sessions per day, except for the days of admission/discharge and Sundays) (Figure 4).

Application of Low-Frequency rTMS

At all hospitals, the rTMS was delivered using a 70-mm figure-8 coil and MagPro R30 stimulator (MagVenture Company, Farum, Denmark). In each 20-minute session, low-frequency rTMS of 1,200 pulses of 1 Hz was applied over the motor cortex of the non-lesional hemisphere, at the site that elicited the largest motor-evoked potentials (MEPs) in the first dorsal interosseous (FDI) muscle of the unaffected upper limb (confirmed by surface electromyographic recording).

	Thursday	Friday-Saturday	Sunday	Monday-Saturday	Sunday	Monday-Wednesday	Thursday
Morning	Admission	Low-frequency rTMS (20min)	No treatment	Low-frequency rTMS (20min)	No treatment	Low-frequency rTMS (20min)	Post-therapy evaluation
		One-to-one training (60min)		One-to-one training (60min)		One-to-one training (60min)	
		Self-exercise (60min)		Self-exercise (60min)		Self-exercise (60min)	
Afternoon	Pre-therapy evaluation	Low-frequency rTMS (20min)		Low-frequency rTMS (20min)		Low-frequency rTMS (20min)	Discharge
		One-to-one training (60min)		One-to-one training (60min)		One-to-one training (60min)	
		Self-exercise (60min)		Self-exercise (60min)		Self-exercise (60min)	

Figure 4. Time schedule of 15-day protocol of combination treatment. Except for days of admission/discharge and Sundays, patients were scheduled to receive two sessions of rTMS and intensive OT daily.

The intensity of the stimulation was set at 90% of motor threshold of the FDI muscle, which was defined as the lowest intensity of stimulation that could activate MEPs in the muscle.

For safety monitoring, a physician at each hospital briefly examined the patient before and after each rTMS session, paying attention to the possible development of adverse effects of rTMS (e.g., headache, nausea, convulsion), appearance of new neurological symptoms (e.g., motor disturbance of the unaffected limbs), or deterioration of upper limb hemiparesis.

Rehabilitative Program of Intensive OT

The program of intensive OT comprised two components: a 60-minute one-to-one training and a 60-minute self-exercise. The one-to-one training, which was provided by an occupational therapist, mainly involved shaping practices (e.g., reaching forward to move a cup from one place to another, writing letters and pictures using a pencil, wiping the surface of the table with a towel, picking up a hairbrush and combing hair) and repetitive task practices (e.g., clay squeezing and molding, pinching small coins, gripping a small ball). In both components of the protocol, patients were instructed to concentrate on use of the affected upper limb.

Although both of these two practices were always included at almost the same proportion of training time (usually 30 minutes for shaping practice and 30 minutes for repetitive task practice) in the one-to-one training program of each patient, the program was tailored by the therapist to suit the individual patient, based on motor function of the affected upper limb and lifestyle of the patients (e.g., occupation, interest, household work). Certain conventional approaches such as facilitation techniques and manual dexterity exercises were also sometimes included in the program. During the hospitalization, the program was modified following motor functional improvement of the affected upper limb.

All the one-to-one training tasks were generally supervised in a face-to-face fashion by an occupational therapist. Positive verbal guidance, encouragement, and feedback were frequently provided so as to achieve the best performance for the selected tasks. The therapists also provided “hands-on” facilitation of movement and inhibition of inappropriate muscle contraction, if necessary.

Following the one-to-one training session, self-exercise was administered in another quiet room without any supervision by the therapist (the room was under continuous video monitoring using built-in-camera for patient safety). Prior to each self-exercise, each patient received specific written instructions for tasks similar to those applied in the one-to-one training, generally involving 3-8 tasks per self-exercise session, with some rest breaks of a few minutes.

After each self-exercise session, the occupational therapists checked and reviewed performance of the tasks through an interview. Problem associated with the tasks were approached aggressively in the following one-to-one training session.

Clinical Evaluation of Upper Limb Motor Function

To determine the effect of the therapeutic protocol on motor function of the affected upper limb, FMA and Wolf Motor Function Test (WMFT) were applied on the days of admission and discharge, and four weeks after discharge whenever possible. The FMA includes 33 items for the evaluation of upper limb motor function (Gladstone, Danells, and Black, 2002; Platz et al., 2005). As each item is rated on a three-point ordinal scale (0=cannot perform, 1=can perform partially, 2=can perform fully), 66 points is the maximum possible score for motor performance of the upper limb. The WMFT includes 15 timed tasks for the evaluation of upper limb motor function, with the performance time of each timed task recorded (Morris, Uswatte, Crago, Cook, and Taub, 2001; Wolf et al., 2001). When the task is not completed within 120 seconds, the performance time of the task was recorded as 120 seconds. For statistical analysis, the mean value of WMFT performance time of 15 tasks was transformed to a natural logarithm as WMFT log performance time, to normalize the skewed distribution of the data, as applied in the analysis of data of the EXCITE trial (Wolf et al., 2006).

CLINICAL RESULTS

By the end of January 2011, 204 post-stroke patients had received the protocol at some of the above mentioned hospitals. In this section, we describe the clinical results of the protocol in these patients (Kakuda et al., 2012).

Clinical Features of Studied Patients

As shown in Table 2, the mean age of the patients at admission was 58.5 ± 13.4 years. The mean time between stroke onset and the intervention was 5.0 ± 4.5 years. Stroke was classified into intracerebral hemorrhage in 107 patients and cerebral infarction in 97 patients.

Safety and Feasibility of the Protocol

The 15-day treatment protocol was completed by all patients. No significant change in the vital signs was observed in any patients throughout the in-patient treatment. Furthermore, none of the patients developed new symptoms or noticed any deterioration of motor function in the upper limb during hospitalization. In 79 patients who received follow-up evaluation at four weeks after discharge, no new adverse symptoms or signs were recorded after the discharge.

Based on these observations, we concluded that the protocol was safe and feasible.

Treatment Outcome on Motor Function of the Affected Upper Limb

The significance of the median changes in FMA score and WMFT log performance time following the treatment was analyzed using the signed Wilcoxon's rank sum test for paired samples. All statistical analyses were performed using The Statistical Package for Social Sciences, v17.0 (SPSS Inc., Chicago, IL).

Based on the data from all 204 participating patients, the median FMA score increased significantly from 47 (36-54) [median (interquartile range)] points at admission to 51 (42-57) points at discharge (Figure 5). Similarly, the 15-day protocol significantly reduced the median WMFT log performance time from 3.23 (1.70-4.07) to 2.51 (1.36-3.86) (Figure 6).

Age at admission, years	58.5 ± 13.4
Gender	
Females	73 (36)
Males	131 (64)
Time since stroke onset, years	5.0 ± 4.5
Subtype of stroke	
Intracerebral hemorrhage	107 (53)
Cerebral cortical infarction	27 (13)
Lacunar infarction	70 (34)
Side of upper limb hemiparesis	
Dominant hand	124 (61)
Non-dominant hand	80 (39)

Values are numbers (%) or mean ± standard deviation.

In 79 patients who were also evaluated at 4 weeks after discharge, both the increased FMA score and decreased WMFT log performance time remained significant compared to the respective values at admission [FMA: 48 (range, 34-53) points at admission, 51 (38-57) points at discharge, 50 (34-56) points at 4 weeks after discharge; WMFT log performance time: 2.81 (1.42-4.08) at admission, 2.20 (1.25-3.78) at discharge, 2.01 (1.31-3.94) at 4 weeks after discharge]. These results suggested that our proposed 15-day protocol improves motor function of the paretic upper limb and that the improvement is maintained for at least 4 weeks after cessation of the protocol.

Baseline Features Affecting Treatment Outcome

In order to identify the factors that correlated significantly with the outcome (i.e., significant change in FMA score and WMFT log performance time), linear regression analysis was performed using the following five baseline characteristics: age, gender, time since stroke onset, subtype of stroke (intracerebral hemorrhage/cerebral cortical infarction/lacunar infarction), and side of upper limb hemiparesis (dominant hand/non-dominant hand).

*p<0.001.

Figure 5. Changes in FMA score in all studied patients. Bars represent the median, and 5th, 25th, 75th, and 95th percentiles.

*p<0.001.

Figure 6. Changes in WMFT log performance time in all studied patients. Bars represent the median, and 5th, 25th, 75th, and 95th percentiles.

When FMA score or WMFT log performance time was selected as the dependent variable, no significant relationship with any of the five parameters was found, indicating that no clinical factor tested thus far definitely influences the functional response to the protocol.

FUTURE DIRECTIONS IN RESEARCH AND CLINICAL PRACTICE

The present study suggested that the combination treatment of low-frequency rTMS and intensive OT safely improves motor function of the paretic upper limb in post-stroke patients.

However, the described protocol was not necessarily satisfactory for all the patients treated, and further improvements in efficacy and extent of benefit of the protocol are needed to ensure that more patients receive the therapeutic effects.

We have therefore proposed further modifications to the protocol for future clinical use in improving motor functional recovery, and initiated pilot studies to assess the safety and effect of these modified protocols. The ideas involve levodopa administration, botulinum toxin injection, and the application of more potent TMS modalities.

CONCOMITANT ADMINISTRATION OF LEVODOPA

Some neurotransmitters modulate brain plasticity after brain damage. In particular, noradrenaline in the brain seems important for facilitating motor functional recovery in the brain following damage (Boyeson and Feeney, 1989). However, such a molecule can have severe adverse effects on various systems such as the cardiovascular system.

On the other hand, administration of levodopa, which is partly metabolized to noradrenaline in the brain, is considered safe and feasible to increase the brain concentration of noradrenaline (Nutt and Fellman, 1984). A recent randomized, prospective, double-blinded study of post-stroke patients found that levodopa administration of 100 mg daily for three weeks in addition to physiotherapy could enhance motor recovery in post-stroke hemiparetic patients (Scheidtmann, Fries, Muller, and Koenig, 2001).

Furthermore, none of these patients showed severe adverse effects associated with levodopa, indicating its safety and feasibility in such a patient population. Therefore, we hypothesized that concomitant administration of levodopa could further facilitate the beneficial plastic changes in the brain produced by our combination treatment.

In other words, levodopa administration could condition the brain to be more responsive to the combination treatment of rTMS and intensive OT. Figure 7 illustrates our novel protocol featuring levodopa administration (Kakuda et al., 2011b). Patients were scheduled to receive a daily oral administration of 100 mg levodopa for one week prior to admission. If the administration was tolerated for one week, the full 15-day in-patient protocol was commenced, along with levodopa administration. The administration was continued until four weeks after the discharge. We recommend an aggressive administration of levodopa concomitantly with our combination treatment, as such a regimen is easy to clinically administer and is not associated with a high risk of adverse effects.

PRE-TREATMENT INJECTION OF BOTULINUM TOXIN TYPE A

For some patients with marked upper limb spasticity as well as upper limb hemiparesis, it seemed that our current protocol of combination treatment did not work well (Kakuda et al., 2011c).

For such patients, a focal injection of botulinum toxin type A (BTXA) prior to the combination treatment is recommended. In recent years, BTXA has been used to control focal spastic hypertonia in patients with upper motor neuron disturbances. Focal injection of BTXA inhibits the release of acetylcholine at the neuromuscular junction and reduces spasticity of

the injected muscle (Brashear et al., 2002; Richardson et al., 2000). Since the BTXA is most effective 4-8 weeks after the injection, the focal injection should be performed at the clinic 4 weeks prior to the in-patient combination treatment (Kaji et al., 2010).

Outpatient treatment		In-patient combination treatment				Outpatient treatment
One week before admission		On the day of admission	2-14 days of admission (except for Sundays)	On the day of discharge		Four weeks after discharge
Start of levodopa administration (orally 100mg/day)						
		AM	Admission	Low-frequency rTMS (20 min)	Post-therapy evaluation and instruction for self-training	Follow-up evaluation
				One-on-one training (60 min)		
				Self-training (60 min)		
		PM	Pre-therapy evaluation	Low-frequency rTMS (20 min)	Discharge	
				One-on-one training (60 min)		
				Self-training (60 min)		

Figure 7. Novel protocol featuring levodopa administration. Patients are requested to receive daily levodopa administration concomitantly with the combination treatment of rTMS and intensive OT.

The selected dose was based on the severity of spasticity and the volume of the target muscles. Based on previous reports, the selected target muscles were in the following order: biceps brachii muscle, flexor carpi radialis muscle, flexor carpi ulnaris muscle, flexor digitorum superficialis muscle, flexor digitorum profundus muscles, flexor pollicis longus muscle, and adductor pollicis muscle (Brin, 1997). The maximum total dose of injected BTXA was 240 units. The pilot study revealed significant improvement in motor function of the affected upper limb, in addition to a significant reduction in spasticity following the intervention. It is possible that the beneficial effects of our proposed protocol will be reduced with the disappearance of the toxin effect; however, the anti-spastic effect of intramuscular BTXA could be successfully maintained by repeated injections 12-20 weeks apart (Bakheit et al., 2004; Elovic et al., 2008). It is expected that such a procedure can maintain the improved motor function in patients who received our combined therapeutic protocol over a long period of time (beyond the expiration of the first injection of BTXA) when BTXA is injected at regular intervals.

APPLICATION OF MORE POTENT TMS MODALITIES FOR NEUROMODULATION

Recently, certain TMS modalities have been reported to be more powerful than conventional rTMS in modulating brain plasticity, including theta burst stimulation (TBS), rTMS with priming stimulation (primed rTMS), paired-pulse stimulation, and quadro-pulse stimulation (Cardenas-Morales, Nowak, Kammer, Wolf, and Schonfeldt-Lecuona, 2010;

Carey, Anderson, Gillick, Whitford, and Pascual-Leone, 2010; Hamada et al., 2007; Huang, Edwards, Rounis, Bhatia, and Rothwell, 2005; Iyer, Schleper, and Wassermann, 2003; Thickbroom, Byrnes, Edwards, and Mastaglia, 2006). Among these modalities, we suggest the application of TBS and primed rTMS instead of the conventional rTMS used in our current protocol, since the safety of both these other modalities have been confirmed and some reports describing their clinical use are already published. The TBS comprises three pulses of 50 Hz delivered every 200 ms, simulating a theta-like rhythm. The pattern of delivery of TBS (continuous TMS versus intermittent TBS) is crucial in determining whether the excitability of the motor cortex is increased (intermittent TBS) or decreased (continuous TBS), with both deliveries inducing after-effects that last longer than any other known rTMS protocol (Cardenas-Morales et al., 2010; Huang et al., 2005). Other advantages of TBS include the shorter application time and the lower stimulation intensity needed to modulate cortical excitability, compared to conventional rTMS modalities. Therefore, a promising strategy for the application could be continuous TBS over the non-lesional hemisphere instead of the conventional low-frequency rTMS, combined with intensive OT for upper limb hemiparesis after stroke. Confirming the usefulness of primed rTMS, Iyer, Schleper, and Wassermann (2003) demonstrated that immediately preceding 1-Hz rTMS with “priming” trains of 6-Hz rTMS caused significantly greater depression of cortical excitability in the stimulated hemisphere than without such priming. This TMS modality also can be clinically applied as an intervention for suppressing neural activity of the non-lesional hemisphere. In our novel protocol featuring this 6-Hz primed low-frequency rTMS, a session of priming stimulation comprising 10 minutes of intermittent 5-Hz rTMS given in 5-s trains with 25-s intervals between trains (Kakuda et al., 2011a). Immediately following the priming stimulation, low-frequency pulses of 1 Hz were applied for 20 min. The result of a pilot study of combined 6-Hz primed low-frequency rTMS and intensive OT showed the beneficial effect of this protocol for upper limb hemiparesis after stroke.

CONCLUSION

Low-frequency rTMS applied together with intensive OT significantly improved motor function of the paretic upper limb after stroke, and such improvement was not associated with any adverse events. Although its efficacy needs to be confirmed in a randomized controlled trial with a control group, we are confident that the protocol is therapeutically beneficial for post-stroke patients with upper limb hemiparesis. We expect that the efficacy of the protocol could be improved with the introduction of concomitant use of pharmacological approaches and application of more potent TMS modalities.

Chapter 56

EVIDENCE FOR C-REACTIVE PROTEIN AS A PROGNOSTIC INDICATOR FOR ISCHAEMIC STROKE RISK

Giovanni Corso^{1,*}, Edo Bottacchi¹ and Massimo Veronese Morosini²

¹Stroke Unit, Department of Neurology,

²Statistics Department Ospedale Regionale, Aosta, Valle d'Aosta, Italy

ABSTRACT

Background: C-reactive protein (CRP) is a blood marker of inflammation and a hallmark of the acute-phase response. Increased CRP is a known predictor of vascular events in asymptomatic individuals and stroke patients. We assessed CRP levels in addition to traditional risk factors in a cohort of transient ischaemic attack (TIA) patients to examine the relationship of these parameters to the occurrence of ischaemic stroke.

Methods: This is a prospective, longitudinal clinical evaluation of the efficacy of CRP as a prognostic indicator. CRP levels were measured in asymptomatic individuals and in TIA patients. 1024 asymptomatic individuals plus the 208 TIA patients (who met all the inclusion and data-collection criteria) were included in the ROC and AUC analysis, making a total of 1232 samples. A clinical risk score was determined in TIA patients using the ABCD² score. Two models were evaluated: ABCD²-only Model, and ABCD²+CRP Model. The primary outcome was an incident ischaemic stroke.

Results: Within 3.7 years ischaemic strokes occurred in 48/208 patients. The Cox proportional hazards models, after adjustments for conventional risk factors, identified CRP levels ≥ 3 mg/L and ABCD² scores ≥ 4 as independent predictors of stroke. The corresponding AUCs were 0.622 and 0.691, based on ABCD²-only Model and ABCD²+CRP Model, respectively; this represented a statistically significant difference ($p = 0.028$). The absolute Integrated Discrimination Improvement (IDI) was 0.0438 ($p < 0.001$), and the relative IDI was 0.8926. The net benefit (NET) became significant from a predicted probability $\geq 20\%$ and was 0.080 when based on ABCD²-only Model and 0.097 when based on ABCD²+CRP Model.

Conclusions: Routine CRP measurements in the acute phase might be a useful tool for identifying TIA patients who are at a higher risk of ischaemic stroke.

Keywords: cardiovascular diagnostic technique, transient ischaemic attack, blood proteins, stroke

INTRODUCTION

Biomarkers, such as C-reactive protein (CRP), which is a peripheral marker of inflammation, might represent a mediator of vascular disease [1]. CRP plays an important role in the development of cardiovascular disease [2, 3]. There is growing evidence that CRP is also a marker of generalized atherosclerosis [4]. Several papers that evaluated its role in ischaemic disease have been published in the past 10 years [5-8]. CRP levels have been measured in patients affected by stroke to facilitate the understanding of its role as a predictor of further cardio- and/or cerebro-vascular events [3-7].

The JUPITER trial shows that the use of rosuvastatin in patients with high CRP level has a significant impact both in reducing the CRP level and in lowering future vascular events [9]. The role of CRP as a marker of ischaemic stroke has been less extensively studied in comparison to coronary artery disease [1-3, 8].

According to published guidelines there is not sufficient evidence to recommend measurement of CRP in the routine evaluation of cerebrovascular disease in primary prevention [8]. In secondary prevention of stroke elevated CRP adds to existing prognostic markers, but it remains to be established whether specific therapeutic options can be derived from this [8].

There have been few studies that evaluated biomarkers exclusively in patients with transient ischaemic attacks (TIA), limited data have been published, and consensus on the significance of CRP levels in TIA patients remained elusive [10, 11]. The risk of stroke after a TIA can be predicted by scores incorporating age, blood pressure, clinical features, duration, and diabetes (ABCD²-score).

The accent on TIA is due to the early elevated risk of stroke (estimates suggest that approximately 20% of strokes are preceded by TIA) [12, 13]. The ABCD system was designed to predict early risk of stroke after TIA [14]. Current international guidelines have adopted this system in the risk stratification of TIA patients and recommend immediate hospitalisation of patients with an ABCD² score ≥ 3 [15] or an ABCD² score ≥ 4 or with crescendo TIA within the previous 7 days [16]. This score have the advantage of using easily assessable clinical variables.

Despite the development of clinical risk prediction scores, such as the ABCD² score, risk stratification remains imperfect. Doctors in the emergency setting need to rapidly and reliably obtain data for each patient for the development of individualised patient risk profiles and the implementation of clinical management plans tailored to each patient. With these considerations, we designed a study to test the hypothesis that a refinement of the ABCD² score by adding a biomarker (CRP) increases the predictive value of the ABCD² score.

METHODS

Two models were evaluated: ABCD²-only Model, and ABCD²+CRP Model. ABCD²-only Model was designed on the ABCD² prognostic score, and the score was calculated on the basis of the following: age (≥ 60 years, 1 point); blood pressure at presentation (SBP ≥ 140 mmHg or DBP ≥ 90 mmHg, 1 point); clinical features (unilateral weakness, 2 points; speech disturbance without weakness 1 point; and other symptoms, 0 points); duration of symptoms (≥ 60 minutes, 2 points; 10 to 59 minutes, 1 point; and < 10 minutes, 0 points); and presence of diabetes (1 point). The ABCD² scores were categorised into low (0 to 3) and high (≥ 4) risk. The duration of symptoms was determined using the last known time point when the patient was in normal condition as the reference point. When multiple TIAs occurred during the study period, the first event was used for calculation of the ABCD² risk score. The ABCD²+CRP Model was designed by adding the CRP value to the ABCD² score.

Subjects and Inclusion Criteria

This study included an analysis of the Cerebrovascular Aosta Registry (CARE) data, inclusion criteria, data collection and follow-up methods were previously described [17]. Baseline measurements were obtained between January 1st, 2004 and December 31st, 2008, and consisted of data related to the event, as well as clinical features that included gender, age, blood pressure, and visits to the Emergency Ward (EW) or to a Specialist Centre (SC); data were collected using a standardized case report form. A TIA was defined as a brief episode of neurological dysfunction that was caused by a focal disturbance due to brain or retinal ischaemia that lasted for less than 24 hours without evidence of infarction [18]. Stroke was defined as “rapidly developing focal (or global) clinical signs of cerebral dysfunction that lasted more than 24 hours with no apparent cause other than a vascular origin” [19]. The following variables were systematically assessed: demographic variables, medical history, physical examination, routine blood biochemistry, early cerebral CT scan and/or magnetic resonance imaging (MRI), carotid ultrasonography, electrocardiogram (ECG), Holter ECG, echocardiography (if indicated), and stroke preventive treatments. Patients with transient dizziness, isolated vertigo, epilepsy, acute confusional state, isolated diplopia, generalised weakness, and syncope were excluded. For the current study, we selected all patients with a final diagnosis of TIA, based on the consensus opinion of two stroke neurologists. Inclusion criteria included a TIA with a CRP measurement within 48 hours after symptom onset. Cases that involved chronic inflammatory disease, cancer or infection before or after the TIA were excluded. All possible predictor variables, such as hypertension, history of myocardial infarction (IHD), atrial fibrillation (AF), diabetes, smoking, and body mass index (BMI), were recorded (Table 1). Patients were treated according to the current guidelines. This included life-style counselling, antihypertensive drugs, antithrombotic agents, statins, as well as specific interventions tailored to the etiology. If carotid stenosis was $\geq 70\%$, the patient was a candidate for carotid intervention within 2 weeks. One thousand twenty-four asymptomatic individuals plus the 208 patients (who met all the inclusion and data-collection criteria) were included in the ROC and AUC analysis, making a total of 1232 samples.

Table 1. Demographic data, cardiovascular risk factors and baseline laboratory parameters according to the CRP cut-off

	CRP <3 mg/l	CRP ≥3 mg/l	P values
Patients, n	79	129	
Mean age, years	69.7 (66.5-72.8)	73.7 (71.5-75.9)	0.018
Gender (M/F), n	36/43	64/65	NS
Mean glucose, mg/dl	100.9 (97.3-104.5)	115.5 (107.1-123.9)	0.005
Mean cholesterol (LDL), mg/dl	120.5 (112.3-128.6)	125.7 (117.9-133.5)	NS
Mean BMI	24.6 (23.9-25.2)	26 (25.3-26.7)	0.002
Risk factors (n,%)			
Hypertension*	69 (87.3%)	117 (90.7%)	NS
Diabetes*	9 (11.4%)	35 (27.1%)	0.007
AF	15 (19%)	25 (19.4%)	NS
>2 risk factors	14 (17.7%)	40 (31%)	0.034
Clinical features (n,%)			
Unilateral weakness	22 (27.8%)	46 (35.7%)	NS
Speech disturbance without weakness	43 (54.4%)	68 (52.7%)	NS
Other	14 (17.7%)	15 (11.6%)	NS
Duration of symptoms (n,%)			
<10 min	13 (16.5%)	12 (9.3%)	NS
10–59 min	51 (64.6%)	84 (65.1%)	NS
≥60 min	15 (19%)	33 (25.6%)	NS
ABCD2 at admission (n,%)			
Score 0–3	35 (44.3%)	30 (23.3%)	0.001
Score 4–7	44 (55.7%)	99 (76.7%)	0.001
Symptomatic internal carotid stenosis ≥50% or occlusion (n,%)			
Present	9 (11.4%)	26 (20.2%)	NS
Absent	70 (88.6%)	103 (79.8%)	NS
Secondary prevention therapy at discharge (n,%)			
BP-lowering	55 (69.6%)	97 (75.2%)	NS
Antithrombotic drugs	67 (84.8%)	103 (79.8%)	NS
Warfarin	11 (13.9%)	20 (15.5%)	NS
Statins	13 (16.5%)	21 (16.3%)	NS
Carotid endarterectomy	2 (2.5%)	7 (5.4%)	NS

*systolic blood pressure ≥ 140 mm Hg and/or diastolic blood pressure ≥ 90 mm Hg, or current use of antihypertensive medications

• if fasting glucose ≥ 126 mg/dL or current use of blood sugar-lowering drugs.

BLOOD SAMPLING AND DETERMINATION OF CRP LEVELS

Blood samples were drawn within 48 hours after symptom onset and were blindly coded. In the laboratory of our hospital, a Roche automated Modular P analyser was used to measure CRP concentrations, according to the CRPLX test. A concentration ≥ 5 mg/L was defined as pathologically increased according to the reference values of our laboratory. CRP measurements were performed by an independent observer who was blinded to the clinical

characteristics of the patients. Control blood samples were obtained from an age-matched population without any history of TIA or stroke, but with risk factors that were similar to the analysed patients (1024 asymptomatic individuals were recruited from a project on stroke prevention, the PrATO, which was simultaneously ongoing in the Aosta Valley territory).

Carotid Ultrasonography

All patients underwent longitudinal 2-dimensional ultrasound examinations of the carotid arteries to evaluate the presence of plaques and to quantify the degree of stenosis. The examinations were performed by a vascular neurologist with an ESAOTE MyLab 70 XVision (Esaote, Genoa, Italy). The internal and common carotid arteries were classified as follows: 'normal', '< 50% stenosis', '50-69% stenosis', '≥ 70% stenosis but less than near occlusion', 'near occlusion' or 'occlusion' [20]. Stenoses that were ≥ 50% were considered symptomatic when they were ipsilateral to the ischaemic field. TIA patients were classified into 2 groups: a) no atherosclerosis or '< 50% stenosis' and b) from '≥ 50 stenosis' to 'occlusion' Patient Follow-up and Outcome Measurements. An independent neurologist followed up with each patient using a questionnaire that investigated the occurrence of new cerebrovascular events; complete data collection was assured by the analysis of the CARE stroke registry. The primary end point was an ischaemic stroke. Outcome was analysed until June 30st, 2011.

Statistical Analysis

The ROC curves were plotted for two models: Model ABCD²-only and Model ABCD²+CRP. If the model predicted and individual would have an ischaemic event within 3.7 years, but did not, it was considered a false-positive. We evaluated the improvement in model performance introduced by the inclusion of CRP value. The increase in the area under the receiver operating characteristic curves (AUC) was evaluated and tested for significance using the test proposed by DeLong et al. [21]. The usefulness of the new marker (CRP) was evaluated by the prognostic model described by Pencina et al. [22] and Vickers et al. [23]. The plasma concentration of CRP followed a log-normal distribution, and all CRP data were log-transformed for analysis.

Data are presented as the mean or the median, with the corresponding 95% CI or the interquartile range, as appropriate. We used the χ^2 test to compare the differences in the proportions of categorical variables, the Student's T test for continuous normally distributed variables (age, serum cholesterol) and the Mann-Whitney test for continuous non-normally distributed variables. P-values ≤ 0.05 were considered to be statistically significant for each test. We performed a univariate analysis of cardiovascular risk factors and recognised prognostic indicators of stroke, including the CRP levels, using a Cox proportional hazard regression model. Multivariate Cox regression models were performed to identify independent predictors of ischaemic stroke.

Ethics

The Medical Ethics Committee of Regional Hospital, Aosta Valley approved the study. Informed consent was obtained from all patients.

RESULTS
